Major Department: Electrical Engineering

This dissertation addresses the problem of finding the optimum design of electric motors used as actuators in robotic manipulators and in manufacturing machines. The optimization may provide a minimum time of operation and/or minimum losses of energy for the actuation.

The development of design technologies is reviewed, yielding a recommendation for a hierarchical procedure for motor design using small computers.

Information from the catalogues of 1100 motors was organized into a computer database, "MOTOR-DB." Analysis of the database shows that the DC PM motor has the best performance characteristics among all types of motors. Further analysis reveals the possibility of the existence of

a unique motor configuration, different from existing ones; dimensions, and with better performance characteristics.

The design of a generalized electric motor is formulated using a doubly excited magnetic field system. The generalized examples of transformer and synchronous motor designs lead to an important result: there exists an optimum machine configuration which remains unchanged when the power of the motor is changed over a broad range.

The design of a DC PM motor is optimized for minimum weight, or losses, or a combination of both objective functions. The design procedure is developed, and results are compared for two different materials (ferrite vs. rare earth PM) and for two different structures (internal vs. "outside-in"). The comparison shows the DC PM motor with a rare earth magnet is an "inside-out" structure with a definite "length/diameter" ratio to be a more desirable solution for a robotic application because the weight and inertia are reduced considerably under the condition of reduced time of operation.

The time of operation is reduced using the hierarchical design procedure and using the constraint of maximum bending stress of the gear teeth. The time of operation is reduced by matching load and actuator.

The results of the research help to improve the method of electric motor design as well as the performance of the mechanical equipment which is driven by the motor.

CHAPTER I INTRODUCTION

1.1 Problem of Optimum Design of Electric Motors

Since the possibility of obtaining mechanical motion using electromagnetic means was discovered by Faraday in 1821 [1], electric motors have become the most versatile and efficient devices for electromechanical energy conversion. Thus, electric motors are being used in all areas, and design techniques have been developed by manufacturers to improve the performance characteristics while maintaining the specifications of the motors.

The performance of a motor can be determined by its efficiency [2-4], acceleration [5], speed-torque characteristics, and the temperature of the winding in a variety of work-regimes. Most of these parameters are related to the weight and losses of a motor. Another way of judging the motor performance at the stage of motor selection among many motors is to compare the modified parameters, such as torque per weight (T/W) [6] or power per weight (P/W) [7-11]. These parameters can better characterize the energy conversion capacities of the motor via the values of torque or power to be produced by the unit weight of the motor. The specifications of the motor are represented by output power, operating voltage, and rated speed.

The word "design" means selecting principles of operation, geometry, dimensions, and materials which can satisfy the specifications and the performance requirements. There is an infinite number of possible design solutions. The optimum design is determined as the most economical and most suitable solution among the multiplicity of admissible designs. The criteria is the optimum design or is the selection of a motor from the list of available choices can be cost, weight, or losses of the motor combined with the satisfaction of the requirements of the work-regime (such as the temperature or the time of operation). Each criterion can be used as a cost function or as objective function in optimum design.

The approaches to the design procedure changed while the nature of motor applications changed over time and became more diversified in its purpose. In the 1930s and 40s, one motor gave mechanical power to several load devices using a belt as a power transmission device. All of the machines were driven by one motor, and the load on this motor averaged the individual load cycles of different machines. Therefore, at this time each load was not to be specified. In the 1950s and 60s, a single motor started to be used to handle a single machine as users began to individualize the load requirements. There were still many different mechanical operations so it was necessary to average the load with time. The idea of "one-hour-load" and so on appeared in the practice of the design, simplifying the process of

loading with a stochastic load on the shaft. Beginning in the 1980s, several motors were used to operate a single machine or mechanical system, and the load conditions could be determined precisely by individualizing each motor of this system. The ultimate example of this system is an industrial robot where sometimes six to ten motors are used in the robot, and each motor characterizes each motion of the system. In this way, the applications of motors have been specialized to improve the motor performance by matching with load and motor condition.

The motor design can be grouped into two types (as shown in Fig. 1-13), which correspond to the status of knowledge of the individual customer and his requirements.

TYPE I: Individual customer is unknown, so the general requirements from a group of similar customers will be formulated.

TYPE I(a): Individual customer is known, but the machine to be equipped by a motor is not designed yet.

TYPE I(b): Individual customer is known, and the machine to be equipped by a motor is already designed.

In TYPE I design, the motor will be independent of the customer's requirements. The generalized requirements, listed below, will be used as input requirements.

1. The average load torque on the shaft and the variation.

2. The average gear ratio in the machine and its variation.
3. The average inertia of the machine and its variation.
4. The typical cycles of operation.

Under all these conditions, the motor should be designed to be most effective while maintaining the above requirements.

In TYPE IIA design, only the output motion of the machine to be designed is described, and the load characteristics are given as follows:

1. Load torque, speed = f (time)
2. Displacement
3. Velocity trajectory
4. Load inertia

In this case, the motor torque and gear ratio are selected to provide the minimum time of operation. After this, the motor should be designed optimally to minimize weight, losses, or cost of motor under the obtained motor torque.

In TYPE IIB design, all the mechanical information about the machine can be obtained:

1. Load masses, inertia = f (x , y)
2. Load masses, torque = f (θ , $\dot{\theta}$)
3. Speed and dynamic torque dependence on time are known
4. Gear ratios are known

This motor should be designed to minimize weight, losses, or cost, and the above conditions are to be maintained.

This study will concentrate on the motor design for actuators in robotic manipulators and automated manufacturing systems. Since the robots of today employ almost every kind of electric motor, the technical and economic characterization of motor applications produces a clear trend toward higher performance drives.

The ideal actuators for manipulators must provide high productivity, low initial cost, accuracy, uniformity of motion, low losses, and high reliability. Actually, it is not possible to achieve the best values of all of these properties, as each superior characteristic requires a compromise in the design of robotic actuators. The economics of robot applications demand that a robot have a sufficient productivity to pay for itself in a short time. The actuator systems in present manipulators have the following inherent problems:

1. 40-60% of work is for carrying its own weight;
2. 40-60% of the weight is its actuators, gearsboxes and supplemental equipment;
3. There is a very wide range of dynamics;
4. The main factors of errors are
 - a. Backlash of gears;
 - b. Losses of energy in the actuator increases the temperature of the motor elements and dimensional expansion will cause performance errors;
 - c. The stiffness of the actuator system will have positional errors which are different from the load.

The theory of electric motor optimum design can be tested in application to the optimum design of the actuator for a multilink manipulator to solve the above problems. Most of the conditions that this actuator is to satisfy are individual, which gives us an opportunity to compare the solution with several conventional alternatives over a variety of performance indices to be achieved.

The following technical requirements can be set:

1. The weight of the motor is to be minimized (ii-ii).
2. The motor is to provide a variety of operational cycles with output path, speed, and acceleration, and jerk restricted.
3. The time of these cycles should be minimized.
4. The motor should not be a source of heat in construction which will damage the assembly of the machine.
5. Actuator volume can be a part of link structure volume and excessive volume reduces dexterity of a manipulator.

These requirements reflect the present state of the art in the design of electric motor drives for robotics.

The study of actuating systems can be divided into two areas: matching the load and actuator, and optimizing the velocity/impedance using proper design of a control system. The control theory has been improved to upgrade the manipulator performance. Tak (11) analyzed the motion control for industrial robots to have minimum positioning error. By

controlling the robot at the joint level, on-line coordinate transformations are eliminated to reduce the computing time; Paul [14] formulated the dynamic equation and solved the control of manipulators so that the specified position trajectory can be achieved by adjusting the feedback gain.

However, the design of the electric motor for the actuator is still separated from the design of each system components as the converter, gearbox, and other components of the control system. To upgrade the whole system, a study to match load and actuator systems should be pre-conducted before the design of control systems. This matching load and actuator system can maximize the performance indices by optimization.

3.2 State of the Art in Electric Motor Design

Although the design technology of the motor has been improved, there are still numerous design techniques in different manufacturing companies because the design technology developed by each company is kept secret from the others. For example, in the Gould Electric Company's report [15], the computer aided design procedure of the induction motor begins just the method of making the input list to the computer program. (The major portion of this method is based on Alger's book [16].) All the papers related to the design algorithm of motors published in the last 20 years are from individual scientists rather than from manufacturing companies.

Before explaining each design method, let us first discuss the general procedure of optimum design. When the motor is to be designed or selected, the type of motor application should be clarified as shown in Fig. 1-1. The known information is different from design types as listed in Table 1-1. Usually, the load duty cycles are in complicated form, so an average of load cycles is taken to determine the rated torque or power. When all the specifications listed upon Table 1-1 are considered at the initial stage of design, the dependencies between all optimum design methods will be set as follows to sequence the design structure in a hierarchical manner:

1. The order of the design hierarchy is decided by the importance of the design criteria which are stated by the customer and by their involvement in different design.
2. The mandatory part of motor specifications are considered first, and the rest will be applied in the next stage of the design.

Based on the type of motor design in Fig. 1-3, the structure of an optimum design procedure is sequenced as shown in Fig. 1-2. This figure shows an example of TYPE I motor design. From the main part of input specifications and the initial values of design variables, the basic motor structure is determined. The design computations will find parameters which are necessary to compute the major criteria. The geometrical constraints, which are to be kept strictly,

and the magnetic constraints will be checked. If these constraints are satisfied, the design is compared with others by the major criterion which is the cost function of an optimum design. If it is not the optimum design, another design will be tried by adjusting the design parameters until the optimum is found. This step of finding the basic structure is called the first step optimization, the second step optimization will find the detailed design parameters for the specific design and the performance check.

The stages development of design technology can be arranged as follows:

1. Conventional design
2. Initial stage of computer use
3. Early stage of optimum design
4. Optimum design

1.1.1. Conventional Design

At the beginning of this century, a motor was designed by the trial-and-error method [8, 18, 17], when the proper values of motor dimensions, number of windings and the voltage level were given, the performance of the assembled motor was checked and modifications tried by some variations of the design parameters from experience.

Figure 1-1 illustrates the conventional design of the DC motor. From the input parameters—power, voltage, and speed—the main dimensions of motor, diameter and length of rotor are determined by the information of similar motors.

Fig. 1-1 Conventional design structure of a GE motor

Then the magnetic flux density and magnetomotive force (mmf) are determined in the same way. In armature design, the number of armature windings and current are computed from the operating voltage, speed, and magnetic flux. After the number of slots per pole is given, the armature pole dimension is computed. To generate the required magnetic flux, the mmf of field winding is computed using the magnetic circuit theory. Then the diameter of field coil and field pole dimensions are computed successively. After all these detailed dimensions of motor are determined, the losses and weight of each part are obtained.

In this design, the experience translated into a number of heuristic rules is applied to make minor changes which may improve the design or correct it to specific requirements. Thus, a good mathematical model of the motor design is not required.

However, the output of a motor depends on the dimensions of rotor, mmf of winding, and the speed of the motor. The values of these parameters must, therefore, be chosen to have optimum cost function, such as weight, manufacturing cost, or losses under a set of operating constraints. Since the mmf of winding can be expressed as a function of rotor dimensions and current density, these rotor dimensions become the most important factors in deciding the cost function or performance of a motor.

In conventional design, these parameters are determined by choosing suitable values obtained from similar motors or

from experience, but these parameters can be determined from the optimization which may be differentiated. Different purposes or cost function. When all of these variables are computed from the information of similar motors or from experience, the final result will not be the optimum design.

1.1.1 Initial Steps of Computer Design

When the computer was first introduced, the majority of the earliest problems to be attempted in the field of motor design by computer were of the formula-translation type. Many of these problems and their solutions have been described in detail in electrical motors. In these cases, the computer served as an aid to the designer by allowing a large number of calculations to be made and more accurate methods to be used and by disposing of the routine and tedious calculations.

Several studies [18-24] are categorized in this type of design. At this stage, they translated the formulas of motor design parameters into computer languages. Based upon the designer's insight and previous experience, a set of dimensions and parameters can be chosen, and if the restrictions are not satisfied, the designer must draw upon his insight to modify the parameters to yield a motor whose performance will meet the specifications. These whole sequences which are similar to those of conventional design are repeated under different values of design parameters to

compare the result. Actually, there were no algorithmic improvements in optimization of motor design.

1.1.3 Early Stage of Optimum Design

As the computer becomes faster, the algorithms of finding the minimum point of cost function using numerical methods improve. In 1964, Krinski and Appotham [32] found the minimum overall cost of an induction motor by an algorithm they developed. This method consisted of assuming numerical values for the $n - 1$ variables and determining the minimum for the n^{th} variable. This value is substituted in the equation, and the minimum is found for another variable at $n - 1$ constant numerical values for the rest, including the minimum point found earlier. This procedure is repeated until all n variables are fixed. But this design problem is treated as one with unconstrained minimization; hence, the results do not correspond to reality.

Anderson [33] used Monte Carlo method to find the minimum cost of a hydroelectric generator. After computing the material cost plus the capitalized cost of losses at a certain starting point, variables or all design parameters are checked to find the cost decreasing directions. If the tries of some variables are successful in reducing cost, the movement continues in that direction; if not successful, opposite directions are tried. These processes will be continued until the minimum point is found. Other studies [34,

30] are similar to these two approaches. The summarized description of each design is shown in Table 1-2.

These methods were the first tries at optimization before the nonlinear programming algorithms were widely developed. These algorithms took more computing time because of slow convergence and sometimes would not converge to an exact optimum point because of the discontinuity of cost functions and constraints. When the systematic search to the optimum point is employed by finding the effective descent direction which was based upon the nonlinear programming algorithms, the global optimum will be achieved. But this clearly showed the direction in which an optimum design would proceed.

1.2.4. Optimum Design

As optimization theory and the search algorithms were more widely developed, the convergence speed was increased by searching effectively the cost function through the decreasing direction. As a result, the computing time is reduced, and a global optimum point is obtained.

Schittinger [31] formulated the transformer design as a problem in nonlinear programming: the cost function of a transformer, which is the sum of material cost and operating cost, is minimized subject to constraints such as efficiency and temperature rise. He used the coordinate search which finds the descent direction by changing a single variable at a time and moves in the descent direction to further reduce the cost function.

THE UNIVERSITY OF CHICAGO

[illegible]

Benarathana and Dean [13, 12] used Sequential Unconstrained Minimization Techniques (SUMP) to optimize the design of the induction motor with respect to the material cost. They used external penalty function to change a constrained problem into a unconstrained one, and a first-order gradient method was employed to move into descent direction.

Benjamin and Seal [14] formulated the optimization problem for large induction motor design using the pattern search and penalty function method. The objective function is the sum of material cost and a specified constrained cost which is related to constraints.

Faloutsos et al. [15] found the optimum design in a different way from the other studies listed above. They checked the variations of the material cost of an induction motor graphically with three variables and chose better design with less cost. The more economical combination of stator stack length, stator diameter, and number of turns per coil could be found by repeating these procedures. This method is simple, but the exact optimum value is hard to find by this method.

Ferre and Revuelta [16] designed a high-speed synchronous motor with respect to minimum size using the pattern search method of Booke and Jensen and an objective function which is a variant, proposed by Benjamin and Seal [14], of the least p optimization. This allows the search to start from nonfeasible regions.

The axial field DC PM motor was designed by Campbell et al., [17]. After the initial analysis of finding the ratio of inner and outer diameter of the motor, the computer-aided design was applied to find the final optimum design. In this analysis step, assumptions were made in order to make the analytic computation possible, but the computer could have solved the problem accurately without any assumption. There were some other studies [18-20] which were similar to those approaches mentioned above.

As can be seen from all these optimization strategies shown in Table 1-3, the algorithms of finding the optimum were improved to search for the global optimum with less computing time. The benefits of these designs were the general purpose nature that satisfy the requirements from broad market customers. In most of the optimum designs, the cost function or objective function is formulated using many variables and optimized with respect to all design parameters at one time. This may make the optimization problem more complicated.

This study divides the whole optimization procedure into several design stages, and each design stage is optimized and linked together into one software. The number of design variables is reduced by expressing some parameters with design variables. As a result, this hierarchical design, with fewer variables, can automatically simplify the design. This kind of hierarchical design has the advantage

or simplifying; a detailed design can be done using the same basic software program.

This dissertation is organized as follows. In Chapter I, the strategies of motor design are reviewed, and two types of motor design are defined. In Chapter II, a database is organized, and the characteristic parameters of motors are compared for different types and for different manufacturing companies. In Chapter III, the generalized electric motor is formulated, and transformer and synchronous motor designs are optimized. In Chapter IV, a DC PM motor is optimized, and the result is compared for two different materials and for two different structures. In Chapter V, the design of DC PM motor for auxiliary manipulator is carried out to reduce the time of operation using the constraint of maximum loading capacity. In Chapter VI, this dissertation is concluded with suggested design structure, conclusions, and suggestions for future research.

CHAPTER 12 REALITY OF DATABASE "MOTOR-USA"

All of the industrial processes require the electro-mechanical energy conversion from a readily available form to another form more suitable for utilization. There is, thus, a large variety of modifications of electric motors used in different branches of industry. The real expressions of these electromechanical models are reflected in sets of data for all the products that share multi-dimensional purposes. The information that may be presented for the customer is concentrated in the catalogues. From these catalogues, one can extract the representative characterization of those motors. Different companies submit different representative characteristics in their catalogues. Therefore, the lacking data should be evaluated separately or are subject to a special enquiry.

An attempt is undertaken to collect, within the framework of a single database, the representative characteristic for a large number of motors (manufactured in USA). The database is described in this study. It is organized on the basis of the collected catalogues for the following purposes.

1. To find out the state of the art in the motor manufacturing industry by computing the

characteristic parameters designating the correlations between T/E and between power, and efficiency and power.

2. To provide the information on motor selection by comparing the characteristic parameters of different types, different speeds and powers.
3. To find out whether the optimum geometry of the motor is actually present in industry.

This database is an integration of the distinct data of all types of electric motors and is stored in RDBMS disks. The access to this database is handled by MSB software which is a computer system for data analysis and provides the following tools needed for data analysis [41]:

1. Information storage and retrieval
2. Data modification and programming
3. Statistical analysis
4. File handling

So this database has the following advantages using the general characteristics of database [42] in the analysis of motor data:

1. Redundancy can be reduced by selecting independent data entries.
2. The data can be shared among different users by using different applications programs in the MSB software.
3. The information in this database can be easily updated.

4. The number of words in the list of characteristic parameters can be easily increased.

2.1 Structure of data

During the preparation of the database, more than 100 manufacturing companies were accessed, and 1818 motors from 34 manufacturing companies were selected based upon the following selection criteria:

1. The general purpose motors, except gear motor, torque motor, and servo motor, are chosen as the target of analysis.
2. The information for weight, power, and speed must be described in the catalogue.

The information in this database includes power, voltage, current, dimensions, efficiency, weight in AC motors and DC motors add inertia of motors to the information of AC motors.

The power range of motor applications in common use are divided into five sub-groups, as shown below, because some types of motors have concentrated in certain power ranges as shown in Fig. 2-1.

- power group C1 = 0.0001 - 0.1 HP
 C2 = 0.1 - 1.0 HP
 C3 = 1.0 - 10.0 HP
 C4 = 10.0 - 100.0 HP
 C5 = 100.0 - 1000.0 HP

Fig. 3-1. Number of nations in each type, genus, and subgenus.

The RPM groups are divided into three subgroups because in AC machines the speed ranges in America are 1725, 1800, and 1850 RPM.

RPM group A = 0-1725 RPM
 B = 1725-1800 RPM
 C = 1800-2100 RPM

The characters 'A'-'E' are the power groups of CI-CR, respectively. From these figures, one can determine the power ranges of major applications in each type of motor because the number of catalogues can explain the number of motors manufactured and used in common use. For example, induction motors are used in all power ranges while synchronous motor and DC motor motors are used in small power ranges for general purposes. In DC motors, series and shunt motors are being replaced by permanent magnet motors, and the development of rare earth materials will accelerate their replacement in the high power range applications.

2.2 Analysis

2.2.1 The Characteristic Parameters

The performance of a motor can be judged and compared with other motors by checking the specifications and comparison criteria as was shown in Table 1-1. The reference for motor evaluation in comparison with other motors can be set by several characteristic parameters. For the selection of motors in actuators for robot, aircraft, and automatic

manufacturing systems, higher power, torque, and efficiency with less weight are the primary criteria.

For that purpose, power per weight (P/W) can be used, which expresses the power capacity that can be transformed from electrical energy into mechanical energy. In the same way, torque per weight (T/W) presents the torque capacity of a motor per unit weight. This T/W ratio is similar to the output coefficient [9, 14, 17] that has been used for a long time as a first step in designing electric motors. The coefficient is defined as the output power per unit speed and unit volume. Since the weight of a motor is proportional to its volume, the output coefficient is proportional to its T/W value. The T/W ratio is more meaningful than P/W ratio because the torque of a motor, rather than its power, decides the size of the motor. Efficiency can be used as a characteristic parameter of motor because it is related to temperature rise and rating of motors.

3.3.1 Comparison of T/W Ratio

From the data, the T/W ratio can be compared in each subgroup. In a very small power group CI (0.0000-0.1 kW), the bar chart in Fig. 3-1a shows the average values of T/W in each type of motor by different IEC groups. Of PM motor shows the highest ratio in IEC group A because PM motors can be applied at very low speed. The induction motor also shows higher ratio because of its simple structure. When the motor is sorted by torque ranges, the PM motor shows the highest

a. Power class = C1 (0.0001 - 0.1 MW)

Fig. 2-2 Comparison of T/M value at each type

a. differential torque (N)

Fig. 2(a) - continued

ratio than any other types of motors, as shown in Fig. 2-2b. This fact shows that the PM motor has better characteristics in small power range with ferrite and alnico materials, but when rare earth PM material is used, the difference between PM motors and other types of motors will become larger.

Figure 2-3 illustrates the dependencies between the average value of T/W ratio and the rated power for induction motors and DC motors. The plain line shows the best values, and the dotted line shows the average values of the ratio. From these curves, the approximated formulas can be determined as shown in Table 2-1. We can use these formulas as references at the initial stage of motor selection. For example, if the power range and speed are known, then the best and mean values of T/W ratios and weights of motors manufactured in industry can be computed successfully. Similar attempts are known from [7]. The detailed values of T/W ratios in each type, speed, range, and power are given in Table 2.2. From these data, one can get more detailed information on the weight and torque of motor that will be used.

2.2.3. Comparison by Performance Coefficient

According to the collected data, the specifications of motors are substantially dispersed, which reflects not only the variety of applications requirements but also some differences in accepted approaches to a design procedure. The trade-off between determination to provide a number of

desirable features such as lighter weight, higher efficiency, acceptable manufacturing costs, and customers' technological requirements, affects the final decision.

To compare the characteristic parameters of motors from different designs, five manufacturers of induction motors are selected in this analysis with the following observations as shown in the next figures.

- A: Westinghouse
- B: Gould
- C: Electric
- D: Marathon
- E: Inland

The mean values of T/W (or η/ω) in the bar chart (fig. 2-4) shows that motors from company "B" have a 25% higher value in RPM group A and 55% in RPM group C than motors from company "C." The trends of manufacturing motors with different powers in each company are illustrated in figs. 2-5a and 2-5b. These graphs show the relation between T/W and power; the ratios are increased as the power becomes larger, but there are a couple of deviating points. This does not mean that the technology of motor manufacturing becomes worse in that power range. It does mean that motor is oversized, e.g., equipped with a bigger frame and core than necessary. This difference becomes larger in RPM group C, which means that at high speed, more different technologies are applied.

Fig. 3-4 P/W for E/W for induction return from CIMS different manufacturing companies

k_1 and group = C (cross area)

Fig. 3-3 - continued

Considering these factors, the difference is still large, as there are still areas to be improved in this T/W ratio which means the weight of the motor can be further reduced.

3.1.4 Characteristic Parameters for DC PM MOTOR

The detailed geometrical analysis was applied to the DC PM motor which has the best T/W characteristics. In Fig. 3-6, the relations among the mean values of T/W, power, and L/D ratio are plotted. In each group, the relations of T/W ratio vs. power is approximated as shown in table 3-3, and these equations are drawn in this figure. As can be seen from this figure, the ratio group 1-3 ($L/D = 1.2-1.4$) has obviously maximum values of ratio. As the ratios are farther from 1:1, the values of T/W ratios decrease more although some deviations are observed.

The relation between efficiency, power, and L/D has a different maximum ratio. The efficiency has maximum relation when the ratio group is 2.0 ($L/D = 1.8-2.2$) as shown in Fig. 3-7 and Table 3-4.

3.2. Conclusions

From the analysis of data, the following conclusions can be obtained:

1. The DC PM motor has the highest T/W ratio among all other types of DC motors. The T/W ratio is as good as for induction motors. This suggests

that PM motors are the most suitable for the robotic applications.

2. The best configuration (4/2) that gives the best performance is different from motors of different application.
3. The characteristic parameter in all types of motors can still be improved by adjusting the geometry or by changing the frames without introducing special techniques of manufacturing.

CHAPTER III
GENERAL APPROACH TO THE PROBLEM OF OPTIMUM DESIGN
OF ELECTRIC MOTORS

3.1 Types of Optimum Design

The optimum design of an electric motor will have different results if the purpose of the motor is changed. Table 3-1 shows different types of motor applications.

The general purpose motor has continuous ratings; the output can be varied indefinitely without exceeding weight-linked limitations. The optimization of this motor is to find a motor design that has minimum initial cost or the sum of initial cost and operating cost. The former is dependent on the weight of the motor, and the latter is dependent on the losses of the motor. This design is constrained by the performance requirements specified by National Electrical Manufacturers Association (NEMA).

In special purpose motors, the motor for actuators in a robotic manipulator [8], [9] will be designed to have minimum weight because a motor with less weight will have less load inertia reflected to the next joint motors, and the motor will reduce energy consumption. The optimum design is constrained by higher peak torque in addition to the standard performance requirements. An electric vehicle [10] is similar to the

Table 3-1 Types of motor applications

Purpose	General purpose	Special purpose motors	
		Manipulator	Electric vehicle
	For general purpose or most of the functions	motors for total or one arm driving other motors at rest point	transmission for transfer the vehicle including the weight of the motor
Power source	Motor or battery	Gas	battery
Body style	vertical	front attachment	long attachment
Dynamic process	load, speed or position constant	weight	weight or weight + force
		1) standard operating requirements 2) higher peak torque 3) higher temperature run for the same ambient class	1) standard operating requirements 2) higher peak torque 3) higher temperature run for the same ambient class
			1) ambient temperature for long rated voltage 2) starting of full winding a synchronous

robotic applications except that the power source is a battery and the operating voltage is low, which will make the objective function the sum of the weight and the losses of the motor. The crane motor [44] is another type of special purpose motor. This motor can usually be applied to the motors which carry out the task illustrated in table 3-1. Crane motor requirements are often very severe and require a high standard of reliability to ensure uninterrupted service as well as safety to personnel and equipment. Motor design must, therefore, have maximum reliability with increased cost and weight. This motor will have an ample metal enclosure with adequate insulation and housing of the coil windings and connections. The problem of protecting the resistor can be solved by reducing the losses of motor. One can see how the difference in the application affects the accepted values of T/ω or s/ω .

3.2 General Problem of Electrical Machine Optimization

3.2.1 Modeling and Formulation of Magnetic System

The doubly excited magnetic field system with two electrical terminal pairs and rotational mechanical displacements will be modeled and optimized as a general form of electrical machine as shown in fig. 3-1. When there is no airgap, this system will be changed into a pot core transformer. This system will be simplified to have the following assumptions without loss of generality.

Fig. 3-1. Doubly excited magnetic field system

1. The reluctance of the core material is negligible.
2. The permeability of the core material is constant which means that the operating point is in the linear region of B-H curve.

Based upon above assumptions, the radial magnetic field in the air-gap can be expressed in terms of the angular variable θ , as in Fig. 3-1, by using the magnetic potential equation.

$$F_m/2g = N_1 i_1 \cos \theta - N_2 i_2 \sin (\theta - \phi) \quad (3.1)$$

where

g = air-gap length

N_1, N_2 = number of turns in primary and secondary windings

i_1, i_2 = currents in primary and secondary windings

ϕ = angular difference in two windings

The magnetic flux density in the air-gap is then determined from eq. (3.1) as

$$B_r = \mu_0 B_T = \mu_0 \left(\frac{N_1 i_1}{2g} \cos \theta - \frac{N_2 i_2}{2g} \sin (\theta - \phi) \right) \quad (3.2)$$

The magnetic flux linkage cut by the primary winding can be determined from the integration

$$\begin{aligned} \psi_1 &= \int_0^{2\pi} B_r B_p \omega r^2 d\theta \\ &= B_{11} i_1 + B_{12} i_2 \cos \phi \end{aligned} \quad (3.3)$$

where

$$L_{11} = \frac{\mu_0 \pi R_1^2}{2l}$$

$$L_{12} = \frac{\mu_0 \pi R_1 R_2}{2l}$$

In the same way the flux linkage in the secondary winding is

$$\begin{aligned} \lambda_2 &= \int_0^{2\pi} B_2 B_2 l d\theta/2 \\ &= L_{21} i_1 \cos \theta + L_{22} i_2 \end{aligned} \quad (12.8)$$

where

$$L_{21} = \frac{\mu_0 \pi R_1 R_2 l B}{2l}$$

$$L_{22} = \frac{\mu_0 \pi R_2^2 l B}{2l}$$

When the secondary winding is rotated, the mutual inductance term is changed at each angular position which generates the torque on the winding. The magnetic flux in the secondary winding is obtained from the integration

$$\begin{aligned} \psi_2 &= \int_0^{2\pi} B_2 l d\theta/2 \\ &= \frac{\mu_0 l B}{2l} (R_1 i_1 \cos \theta + R_2 i_2) \end{aligned} \quad (12.9)$$

The conservation of energy in the magnetic circuit can have the following relation

$$\begin{aligned}
 dW &= \sum i_1 d\psi_1 + \sum i_2^j d\psi_j \\
 &= i_1 da_1 + i_2 da_2 + T^2 dt
 \end{aligned}
 \quad (1.6)$$

The energy stored in the air-gap is

$$W = \frac{1}{2} i_1^2 \frac{1}{g} + i_2 i_1 a_2 \cos \theta + \frac{1}{2} i_2^2 \frac{1}{g} \quad (1.7)$$

The torque which is the partial derivation of energy with respect to the angular displacement can be expressed as

$$\begin{aligned}
 T &= \frac{\partial W}{\partial \theta} \\
 &= -i_2 i_1 i_1 i_2 \sin \theta
 \end{aligned}
 \quad (1.8)$$

The average torque around the periphery inside the stator is

$$\begin{aligned}
 T_{av} &= \frac{1}{2\pi} \int_0^{2\pi} T \, d\theta \\
 &= -\frac{i_2^2 N_1 N_2^2 \pi B_1^2 i_1}{2g}
 \end{aligned}
 \quad (1.9)$$

If this magnetic system can be rotated with speed ω by other additional device (ex. DC converter in the robot AC rotating magnetic field), the output power of this rotating system will be

$$\begin{aligned}
 P_{out} &= T_{av} \omega \\
 &= -\frac{i_2^2 N_1 N_2^2 \pi B_1^2 \omega}{2g}
 \end{aligned}
 \quad (1.10)$$

1.2.2. Design

1.2.2.1. Input and design variables

The general approach for the optimum design of an electric motor was illustrated in Fig. 1-2. For this system design, the output power, operating voltage, and rated speed will be chosen as input parameters, and the independent design parameters must be chosen carefully. Otherwise, more constraints should be applied to this design, which will make the optimum design still more complicated. Thus, diameter (D) and length (L) of the rotor, window areas of primary and secondary windings (A_1 , A_2), and current densities of both windings (J_1 , J_2) can be chosen as design variables because these parameters will govern the weight, efficiency, and the cost of the motor noticeably. Other parameters, such as number of poles, number of slots per pole (K_{as}), and air-gap length (g) are assumed to be fixed for each motor. And the thickness of the stator can be expressed as a function of design variables.

1.2.2.2. Objective Function

The objective function of this system can be weight, or losses, or a combination of both, depending upon the purpose for which the machine is going to be used. The weight of this system will be

$$W = W_1 + W_2 \quad (1.11)$$

where

$$\begin{aligned} W_1 &= \text{iron weight} \\ &= \pi d_1^2 (25+2t_1+2t_2)^2 \\ &\quad + (25+2t_1)^2 (L/4 + \pi d_1^2 (2t_1+2t_2)^2/4 + 2t_2) \end{aligned} \quad (1.12)$$

$$\begin{aligned} W_2 &= \text{copper weight} \\ &= d_2^2 h_2 (2L+22+4t) = d_2^2 h_2 (2L+20) \end{aligned} \quad (1.13)$$

The losses of this system will be

$$P_{\text{loss}} = L_1 + L_2 \quad (1.14)$$

where

$$\begin{aligned} L_1 &= \text{copper losses} \\ &= \pi^2 f^2 h_1 (2L+22+4t) + \pi^2 f^2 h_2 (2L+20) \end{aligned} \quad (1.15)$$

L_2 = core losses

$$= C_1 W_1$$

C_1 = core losses per unit weight

1.1.2.1. Formulation in optimization

The optimization of this system will be done under the following constraints—

1. Geometrical constraints

Width of teeth in series and stagger = ϕ

Available flux path in series = 1

2. Magnetic constraints

Magnetic flux density < saturation density

1. Thermal constraints

Maximum temperature < limit temperature

The geometrical constraints should be strictly adhered too otherwise, the motor cannot be made.

3-2.3 Optimization strategy

After all these preparations, the objective function will be optimized while maintaining the constraints. The procedure of optimization was illustrated on Fig. 1-2.

3-2.3.1 Penalty function method

There are many techniques available for the unconstrained optimization problems, but the special property of objective functions of motor make it hard to select the proper optimization algorithm. The characteristics of the motor objective function are as follows.

1. The number of turns of the winding have to be an integer value.
2. The variables of all equations are linked together, as it is very difficult to differentiate.
3. The variables are to be chosen under the constraints.
4. As a result, the objective function is not continuous.

Therefore, the algorithms using derivatives [17-18] are not suitable for this purpose. A penalty function method that transforms the constrained problem into a sequence of unconstrained maximization problems can be used in this study. There are several reasons for the appeal of penalty function

formulation, the main reason, which can be observed in Fig. 3-3, is that the sequential nature of the method allows a gradual approach to the minimality of the constraints. In addition, this algorithm for the unconstrained minimization of rather arbitrary function is well studied and is generally quite reliable.

The general form of nonlinear programming with equality and inequality constraints can be stated as follows:

$$\text{Minimize } f(\mathbf{x}) \quad (3.37)$$

$$\text{s.t.} \quad g_i(\mathbf{x}) \leq 0 \quad \text{for } i = 1, \dots, m$$

$$h_j(\mathbf{x}) = 0 \quad \text{for } j = 1, \dots, k$$

Penney and McFarquhar (1965) used the following expression for the augmented objective function. At the beginning of the k^{th} iteration, the augmented objective function is

$$\phi(\mathbf{x}, r^k) = f(\mathbf{x}) + r^k \sum_{i=1}^m \frac{1}{2} \frac{g_i^2(\mathbf{x})}{1 + g_i^2(\mathbf{x})} + \frac{1}{2} r^k \sum_{j=1}^k h_j^2(\mathbf{x}) \quad (3.38)$$

The penalty term, r^k , is chosen such that its value will be small at points away from the constraint boundaries and will tend to be infinity as the constraint boundaries are approached. Thus, once the unconstrained minimization of the objective function $\phi(\mathbf{x}, r^k)$ is started from any feasible point, the subsequent points generated will always be within the feasible domain since the constraint boundaries act as a barrier during the minimization process. The penalty term in eq. (3.38) is not defined if the inequality constraint is not satisfied. This may be one problem in using eq. (3.38).

Fig. 3-2 Illustration of penalty function method

Since this equation does not allow any constraint to be violated, it requires a feasible starting point for the search toward the optimum point. However, in many engineering problems, it may not be so difficult to find a point satisfying all the inequality constraints. If $f(x, r^k)$ is minimized for a decreasing sequence of values r^k , the unconstrained minima will converge to the solution of the original problem stated in eq. (3-17) as shown in Fig. 3-2.

3-2.3 Search algorithm

To achieve a rapid convergence to a global minimum of a N variable function, the pattern search method is used in this study. The pattern search of Rosen and Jones [34] is a sequential technique, each step of which consists of two kinds of moves—an exploratory move and a pattern move. The exploratory move starts x^0 as the initial point, and all coordinate directions are searched one at a time to find the descent direction. If a positive displacement of any point does not yield a reduction of the objective function, the opposite direction is tried. At the end of a series of exploratory moves, a new point x^1 can be determined. Now a pattern search is made along $(x^1 - x^0)$ direction and is continued until a minimum is found in that direction as shown in Fig. 3-3. At the end of this pattern search, the procedure is repeated until a global minimum is found.

For the minimization technique in one direction, FIBONACCI search is used. Fibonacci search [35] reduces

Fig. 3-3 Fibonacci search algorithm

the interval of uncertainty about where the minimum lies by eliminating the appropriate interval after comparison of two function values at two Fibonacci points. The detailed flow chart of computer program will be shown in Appendix C. The examples of optimum design will be presented in the next sections.

1.1 Transformer Design

The brief procedure and numerical result will be discussed here, and the detailed derivations will be in Appendix B. Figure 1-1 shows the geometry of a-core transformer which is going to be optimized.

1.1.1 Preparation for Optimization

The input parameters, design variables, objective function, and constraints are expressed as in Table 1-2. All these parameters are expressed as functions of design variables.

1.1.2 Optimization

The optimum design procedure of the transformer is similar to Fig. 1-3 except that the input and design parameters are different. This design will determine the main design parameters, such as the geometry (l_0 , D_0 , D_1), window area and current density. The detailed design can find the diameter of winding and number of turns. For the optimization of the transformer, genetic search was used.

Fig. 3-4. G - open transformer

Table 3-3 Transformer Design

Parameters	Descriptions
Input parameters	1. Induced output VA : S 2. Operating voltage : V
Design variables	1. Length of window coil : l_w 2. Width of square coil : D_w 3. Width of winding part : D_c 4. Current density : J
Weight objective function	$W = W_{cp} + W_{ir}$ where W_{cp} = weight of copper winding $= 4l_{cp}l_w(D_w - D_c)^2$ W_{ir} = weight of core $= 4D_w^2l_w(D_w - D_c + D_c)$
Cost objective	$Z = Z_{cp} + Z_{ir}$ where Z_{cp} = copper winding losses $= \frac{4l_{cp}l_w(D_w - D_c)^2 J^2 R_{cp}}{0.72 \times 10^6}$ Z_{ir} = core losses $= 4l_w^2 D_w^2 \left(\frac{1.1}{10^6} \right) \left(\frac{W_{ir}}{W_{ir0}} \right)^{1.6}$
Constraints	1. Operating magnetic flux density 2. Maximum temperature rise of winding

3.1.1 Results

The weight function and losses function of the transformer are plotted in these dimensions as in Figs. 3-3 and 3-4. These plots show that there exists an obvious global optimum point for each objective function. The numerical results in Tables 3-3 and 3-4 show that the shape of the transformer in optimum design is not changed although the output VA is increased.

3.2 Synchronous Motor with PM Exciter

3.2.1 Preparation for Optimization [11]

The top view of a synchronous motor with a PM exciter is shown in Fig. 3-5. The input parameters, design variables, objective function, and constraints in the optimum design of a synchronous motor with a PM exciter are shown in Table 3-5, and the detailed derivations are in Appendix B.

3.2.2 Optimization

The optimum design procedure was shown in Fig. 3-2, and this design will determine the main design parameters such as diameter and length of rotor, window area of armature winding and current density of armature winding. The optimization was done using pattern search as in transformer design.

3.2.3 Result

The numerical result of optimum design for minimum weight is presented in Table 3-6. The same result with

transformer was found that the shape of rotor is not changed; in other words, the ratio between diameter and length of rotor is the same for a series of different power ranges.

3.3. Conclusions

From all these analyses and results of optimization, we can get the following conclusions:

1. All machines have their own optimum configurations.
2. The optimum configuration is not changed although the power rating is changed.

CHAPTER IV STRUCTURE OF DESIGN PROBLEMS WITHIN WEIGHTEDNESS OF ENERGY

The general problem of electrical machine optimization was shown, and the simplified models in asynchronous and synchronous motor were optimized in Chapter III. This chapter will optimize the DC PM motor with respect to weight, losses of energy and combination of both objective functions in the normal structure of a motor. The motor with an "inside-out" structure will be optimized to compare the advantages of this structure.

4.1 The simplified characterization of DC PM motors

Conventionally wound field DC motors have been the main DC energy conversion device since the discovery of electro-mechanical motion. Recently, the permanent magnet (PM) motors challenged the traditional wound field DC motors in all sizes up to 5 MW [30]. For the last thirty years, the use of PM fields in small DC motors has been increasing to the point where a majority of the motors are now charged with PM motors. Furthermore, the development of the new PM materials also evolved and broadened their applications.

Prior to the PM motors, the three popular types of AC motors for industrial applications were shunt, series, and compound motors. Designers often made compromises in their equipment in order to use one of these three motors. For example, gears and pulleys were often added to reduce the speed of a series motor enough to make the portable equipment practical.

For the proper selection or design, it is necessary to understand the characteristics, advantages, and shortcomings of each type of motor. Table 4-1 shows the collected information of the characteristics of wound field motors. As can be seen from this table, the wound field DC motors have a number of shortcomings.

To see the superior properties of PM materials, let us make a comparison between the PM and wound field methods as illustrated in Fig. 4-1 and Table 4-2.

The volume of field part is proportional to the diameter, D , in wound field method, and is proportional to the square of core dimension, D^2 , in PM field method. The coefficient of volume equation in the PM field is much smaller than that in the wound field method. Thus, the volume of the PM motor is smaller than that of the wound field motor in small power applications. If the power is very low, the volume of the PM motor is much smaller than that of wound field motor. This coincides with the fact that most of the PM motor applications have been confined

Table 4-1. Comparison of wound field DC motors

Class	Advantages	Disadvantages
Shunt motor	1. Relatively good speed regulation up to 200 % 2. Widely of control (voltage & field control) 3. Capability of high torque applications	1. Small starting torque (constant resistance)
Series motor	1. Highest starting torque 2. Higher power per weight ratio 3. Wide speed capability	1. Bad speed regulation 2. Over-speed at light load 3. Small power use
Compound motor	Better than pure shunt motor	1. Complicated control circuit needed

a. RF field method

b. Wound field method

Fig. 4-1 Comparison between RF field and wound field methods

Table 2-1 Comparison of PB and wind field methods

		Wind field	PB field	
Basic equation		$B_z(z) = \sum_{n=1}^{\infty} B_n z^n$	$B_z(z) + B_n z^n = 0$ $B_n = B_z^n + \sum_{m=1}^n B_m$ $B_n A_n = \sum_{m=1}^n B_m A_m$	
Volume of field part		$V_{\text{PB}} = 4A^2 B = 4A^3$	$V_{\text{PB}} = B^2 A_{\text{PB}}$	
B_z 161	1800	$A = 0.446$ $V_{\text{PB}} = 0.694 \pm 0.36$	FWT100	$V_{\text{PB}} = 0.095 \times 10^3$
			SWCO ₁₀	$V_{\text{PB}} = 0.010 \times 10^3$
	1850	$A = 0.431$ $V_{\text{PB}} = 0.590 \pm 0.30$	FWT100	$V_{\text{PB}} = 0.100 \times 10^3$
			SWCO ₁₀	$V_{\text{PB}} = 0.010 \times 10^3$
	4000	$A = 0.893$ $V_{\text{PB}} = 3.240 \pm 0.86$	FWT100	X
			SWCO ₁₀	$V_{\text{PB}} = 0.100 \times 10^3$
	6000	$A = 1.248$ $V_{\text{PB}} = 6.276 \pm 0.90$	FWT100	X
			SWCO ₁₀	$V_{\text{PB}} = 1.480 \times 10^3$

to smaller power ranges! The motors for robotic applications are within these power ranges.

We can also see from these tables that as the magnetic flux density increases, the volume of the wound field motor is increased quite linearly, but in PM field motors, the volume is increased much faster. As the operating point of the PM motor is usually very close to the maximum energy product point.

The advantages of the DC PM motor over the wound field motor are listed below (14-16) with the result of comparison from the database as shown in Table 4-1:

1. Size: The motor diameter of a PM motor is reduced from 144 to 84% and in our database, the diameter of a DC PM motor is 1 HP is 44% less than that of a DC wound motor and 144 less in 3 HP. The reasons for the smaller outside diameter are that there is no bulky field, and the magnets can be assembled by cementing the magnets to the shell.
2. Weight: A weight reduction up to 30% can be expected in the motor due to the smaller diameter with the same size of armature. And in our database, the weight of the PM motor is 44% less than that of a wound motor in 1 HP and 17% less in 3 HP.
3. Efficiency: An increase in the efficiency by up to 15% occurs because the field is generated by a permanent magnet and does not have to be supplied

Table 4-3 Comparison of DC PM motor and shunt motor from the database

	1. SP		2. PP	
	PM	Shunt	PM	Shunt
Diameter (mm)	8.248	8.147	8.279	8.213
Weight (kg)	29.3	33.3	28.9	78.3
efficiency(%)	88.5	79.3	88.3	79.3

4. Temperature: Higher efficiency means cooler operation for the same power, so the PM motor concept is suitable for the equipment where heat losses are problems in operation.
5. Armature reaction: The PM pole piece has a permeability very close to that of air. And when the armature reaction flux enters the core in a PM motor, the flux lines are resisted by a low permeability material. In other words, the PM motor has a very large effective air-gap. So the armature reaction does not distort the main field of the overland magnetism in a PM motor as it does in a wound field motor. As a result, it offers a relatively high starting torque (100% of rated torque), and the performance of a PM motor is a straight line over the operating range.

Considering all these above, the conclusion is the PM motor is quite natural.

4.3 Comparison of Permanent Magnet Materials PM-552

The permanent magnet materials have been developed to have higher remanent flux density, higher coercive force, and higher energy product. There are three major PM families in use--alnico, ferrites, and rare earth magnet. We will consider the characteristics of each PM material.

Demagnetization characteristics of these PM materials aren't commonly used in rotating electrical machines (see chart in Fig. 4-3 together with some new materials of interest). Table 4-4 illustrates the comparison of PM materials.

Alnico magnets have been traditionally employed in electrical machines. The high remanence type, Alnico 5-T, offers potentially higher flux density with good temperature characteristics. However, the very low coercive force requires a very long magnet. Furthermore, the knee in the curve occurs only slightly below the remanent flux density; this will result in the operating point's being forced down the steep part of the demagnetization curve with only a small additional demagnetizing field due to an armature reaction. Another problem concerning this low coercive force is that this magnet must be demagnetized after assembling it to the machine.

Ceramic ferrites are most commonly used in the production of PM motors due to their cost advantage, availability and ease of fabrication into the stator. The demagnetization curve is quite linear over most of the quadrant, and the very low permeability ensures that recoil property will be lost along the same curve rather than within the curve as with Alnico's. Ferrites may be magnetized before assembling because of high coercive force. But the remanent flux density is very low, and they are frequently designed to operate well above the maximum energy point, to get more flux at the expense of additional magnet length.

Fig. 4-2 Degradation characteristics of Fe materials

Table 4-4 Comparison of Fe materials

KIND	ADVANTAGES	DISADVANTAGES
AMPERCO-3	1. LOWEST H_d (3.15 T) 2. GOOD TEMPERATURE STABILIZATION	1. LOWEST H_d (75 MA/KG) 2. LARGE SIZE LONGER MAGNET 3. DECONTAMINATION AFTER ASSEMBLY
FEALITE	1. CHEAPEST 2. EASY FABRICATION 3. HIGHER H_d (140 MA/KG) 4. LOWER H_c (3)	1. LOWEST H_c (20-4 T) REQUIRES LOWER MAGNET
IRON SANDS MAGNET	1. HIGHEST ENERGY PRODUCT (144 kJ/m ³) 2. HIGHEST H_d (2000 A/KG) 3. HIGHER H_c (18-25 T) 4. SUITABLE FOR "INTER-GR" MOTOR	1. HIGHEST MATERIAL COST

Now with FR materials (40-61), were developed about 10 years ago, and their properties, which are almost the best in all areas, are still improving. The properties of these materials which intrigue the motor designer much are the following.

1. Highest energy product: 144 kJ/m
2. Highest tensile force: 144 kN/m
3. Highest moment flux density: 0.45 T
4. High curie temperature: 770°C

The only disadvantage is the price of materials, which limits the design criterion of this type to operation at the maximum energy point to maintain the upper value. With this rare earth material, it is now possible to place the FR field in the rotor.

4.2 Design

Figure 4-1 shows the normal structure and "inside-out" structure of the AC FR motor. The "inside-out" structure is the inverted structure where the structure part is in the stationary part and FR is in the rotor as shown in the figure. The difference in detailed design will be discussed later.

Based upon the general design structure in Fig. 4-1, the optimum design procedure is organized as shown in Fig. 4-2 which illustrates the optimization algorithm, FEM and pattern search, discussed in Chapter III. Most of the

Fig. 4a) Normal structure and "Inside-out" structure of DC PM motor

Fig. 8-4 Basic structure of optimum motor design

procedures are the same as the general structure shown in Fig. 4-2. This figure explains the first step design which decides the optimum motor configuration.

After the input parameters of DC PM motor design are given, which are the specifications of motor performance, the magnetization and core loss curves for selected core are determined using the Chebyshev polynomial approximation [11]. When the EMF is started under given supply parameter V^b , the pattern search which consists of an exploratory move and a Filomonte move was used to find the minimum weight or loss objective function. After the series of minimization procedures, the convergence criterion is checked. If the criterion is satisfied, the optimum design parameters can be obtained, otherwise, this optimization procedure (B) in Fig. 4-3 will be reiterated until the criterion is satisfied.

With these obtained design parameters, the temperature rise of armature winding is to be checked because the armature winding is the source of heat and has the highest temperature in the motor. If the temperature rise is not the same as the machine limit, the current density is adjusted and the optimization procedure (B) in Fig. 4-4 will be started again until it reaches the temperature limit.

Now we will consider the actual design of the DC PM motor with normal and "inside-out" structures. Although both structures are different in configurations, their basic magnetic circuits are the same as shown in Fig. 4-5.

Fig. 4-2 Equivalent magnetic circuit of four pole DC PM motor

4.1.1.2. General description of motor

4.1.1.2.1. Definition of design parameters

The flow chart of computing the objective function which illustrates the design procedure is shown in Fig. 4-6. The input parameters are power (P_{out}), voltage (V), rated speed (ω), and number of poles (P_p) for general purpose motors. The motor for the robotic actuator will have rated torque (T_p) and number of poles (P_p) as input parameters.

It is very important to select the design variables properly; otherwise, the optimization problem becomes complicated and sometimes hard to converge to optimum value. The design parameters finally selected on DC PM motors are shown below:

1. Motor diameter: D
2. Motor length: L
3. Armature window area: A_a
4. Width of magnet: R_{lm}
5. Thickness of field pole: t_p
6. Current density: J_a

4.1.1.2.2. Induced voltage computation

From the given voltage and power, the diameter of winding can be determined using the following basic equations in steady state,

$$V = E_a + I_a R_a \quad (4.11)$$

$$VI_a = P_{out} + I_a^2 R_a \quad (4.12)$$

Fig. 8-6 Flow chart of designing procedure of dc PM motor

where

$$I_a = J_a \pi D_a^2 s / 4 \quad (4.13)$$

D_a = diameter of armature winding

J_a = current density in armature winding

E_g = induced voltage

s = number of parallel paths

$$P_{\text{out}} = E_g I_a$$

The resistance of armature winding, R , can be expressed as

$$\begin{aligned} R &= \pi l / b \\ &= \frac{\pi^2 l_{1L}^2 k_a N_{as}^2}{(4 \pi^2 D_a^2 / 4)^2} \end{aligned} \quad (4.14)$$

where

π = resistivity of winding material

l_{1L} = mean turn length of armature winding

k_a = armature window area

N_{as} = number of armature slots per pole

m = number of pole pairs

Substituting eq. (4.14) into eq. (4.1) yields

$$V_a + \pi D_a^2 s = P_{\text{out}} + I_{\text{cop}} \quad (4.15)$$

where

$$I_{\text{cop}} = J_a^2 \pi^2 l_{1L}^2 k_a N_{as}^2 m \quad \text{copper losses}$$

from eq. (4.5), the diameter of winding can be obtained as

$$D_w = \sqrt{\frac{2P_{\text{out}} + P_{\text{fe}}}{4.5 \times 10^{-4} \pi I_a^2}} \quad (4.6)$$

After the diameter of armature winding is obtained, the induced voltage and magnetic flux can be computed respectively.

$$E_g = V + I_a R_a \quad (4.7)$$

$$\phi = \frac{E_g}{\frac{2\pi N}{60} K} \quad (4.8)$$

where

$$\begin{aligned} N &= \text{total number of turns} \\ &= m N_{\text{ph}} \text{ integer } (N_g / 1000^2 / 4) \\ \omega &= \text{angular speed} \end{aligned} \quad (4.9)$$

4.3.3.3 Thickness of PM

The equivalent magnetic circuit of PM motor was shown in Fig. 4-5. The reluctances of air-gap, stator, armature pole, and field pole can be expressed as a function of geometrical parameters respectively

$$R_g = \frac{g}{\mu_0 \mu_r A_g} \quad (4.10)$$

$$R_{st} = \frac{l_{st}}{\mu_r \mu_0 A_{st}} \quad (4.11)$$

$$R_{fa} = \frac{l_{fa}}{\mu_r \mu_0 A_{fa}} \quad (4.12)$$

$$\mu_{\text{eff}} = \frac{F_{\text{eff}}}{i_2 i_2 K_{\text{eff}}} \quad (4.12)$$

$$K_{\text{eff}} = \frac{F_{\text{eff}}}{i_2 i_2} = \frac{(D + 2\mu_{\text{m}} + i_1 l / \mu_{\text{m}})}{i_2 i_2 K_{\text{eff}}} + \frac{\mu_{\text{m}}}{i_2 i_2 K_{\text{eff}}} \quad (4.13)$$

μ_{m} = effective air-gap (13)

$$= \frac{D_{\text{eff}} + \mu_{\text{eff}}}{\mu_{\text{m}} + \mu_{\text{eff}}} (l + i_2 l)$$

l = air-gap length

$K_{\text{eff}}, K_{\text{m}}, K_{\text{eff}}, K_{\text{m}}, K_{\text{eff}}$ = cross sectional area of air-gap,
magnet, armature pole, tooth,
field pole

μ_{m} = thickness of magnet

$i_1 i_2 i_2$ = permeability of tooth, armature pole, and
field pole

And the magnetic circuit equation can be expressed as

$$F_{\text{m}} = (2\mu_{\text{m}} + 2\mu_{\text{m}} + 2\mu_{\text{m}} + i_2 i_2 + \mu_{\text{eff}}) i_2 \quad (4.14)$$

where

$$F_{\text{m}} = 2\mu_{\text{m}} i_2 \quad (4.15)$$

$$i_2 = \mu_{\text{m}} i_2$$

From eq. (4.14) - eq. (4.15), the thickness of permanent magnet that can generate the magnetic flux will be determined.

$$\mu_{\text{m}} = \frac{F_{\text{m}} + F_{\text{eff}}}{i_2 i_2} = F_{\text{m}} \quad (4.16)$$

where

$$r_1 = i(12k_y + 12k_z + 3k_y^2/2)$$

$$r_2 = i\alpha(12k_yk_z - k_{xy}^2) + 2i(k_zk_yk_{xz})$$

$$r_3 = \frac{\alpha(2 + 3k_{xz} + k_y)}{4k_zk_yk_{xy}}$$

4.3.1.4. Approximations of magnetization and loss curves

To determine exactly the loss losses and the magnetization curve, the Chebyshev polynomial and curve fitting are used. The results of approximations are shown in Figs 4-7 and 4-8. The actual data represented by "." are quite close to the approximated data.

4.3.1.5. Objective function

The objective function of the design in this study will use the weight, losses, or combination of both

1. Weight

Structure part

$$W_{st} = W_{sw} + W_{ai} + W_{cy} + W_{al} \quad (4-10)$$

where

$$W_{sw} = \text{structure winding weight} = 0.025k_{cy}k_{al}k_y$$

$$W_{ai} = \text{insulator weight}$$

$$= 0.12Lr(0.025k_{sw}) = k_y18k_{cy}k_{al}$$

$$W_{cy} = \text{pole weight} = 0.12Lr(10 + 18k_{al})^2/4$$

Fig. 4-7 Approximation of magnetization curve

Fig. 4-4 Approximation of loss curve

$$\begin{aligned}
 W_{\text{tooth}} &= \text{tooth weight} \\
 &= 0.11 D^2 L_{\text{tooth}} / 4 = W_{\text{tooth}} = W_p W_{\text{tooth}} D_{\text{tooth}} D_{\text{tooth}} W_{\text{tooth}}^2
 \end{aligned}$$

Flank part

$$W_f = W_{\text{tooth}} + W_{\text{tooth}} \quad (4-17)$$

where

$$W_{\text{tooth}} = \text{tooth weight} = W_p D_{\text{tooth}} L_{\text{tooth}}$$

$$\begin{aligned}
 W_{\text{tooth}} &= \text{tooth weight} \\
 &= \frac{W_p L_{\text{tooth}}}{4} (10 + 19 + 17 r_{\text{tooth}} + 17 r_{\text{tooth}})^2 = (20 + 19 + 17 r_{\text{tooth}})^2
 \end{aligned}$$

Total weight

$$W_t = W_p + W_f \quad (4-18)$$

2. Losses

Copper losses of machine winding

$$P_{\text{copper}} = I^2 R_{\text{tooth}} + I^2 R_{\text{tooth}} \quad (4-19)$$

Copper losses

$$P_{\text{copper}} = P_{\text{tooth}} + P_{\text{tooth}} \quad (4-20)$$

where

$$P_{\text{tooth}} = \text{tooth copper losses} = I_{\text{tooth}}^2 R_{\text{tooth}}$$

$$P_{\text{tooth}} = \text{tooth copper losses} = I_{\text{tooth}}^2 R_{\text{tooth}}$$

$R_{\text{tooth}}, R_{\text{tooth}} = \text{tooth, tooth copper losses per unit weight}$

Total losses

$$T_{\text{loss}} = T_{\text{sp}} + T_{\text{sw}} \quad (4.31)$$

3. The combination of these two cost functions can be expressed using weighting factor k :

$$\text{COT} = (1 - k)W_1 + kT_{\text{loss}} \quad (4.34)$$

4.3.1.3 Constraints

The constraints for the optimum design of a DC PM motor which are similar to those in chapter III, are listed below.

1. The width of armature teeth and armature winding area are positive:
 $W_{\text{at}}, A_a > 0$
2. The magnetic flux density in teeth, armature yoke, and field yoke is less than the limit,
 $B_t, B_{\text{at}}, B_{\text{fy}} \leq B_m$
3. The temperature rise of armature winding is the same as the temperature limit

Using these constraints, the temperature rise is not computed easily because the heat dissipation is related to the structure, environmental conditions, and time. This will be discussed in detail in the next section.

4.3.1.3 Thermal optimization

4.3.1.3.1 Heat transfer between rotor and stator. The heat transfer characteristics of air-gap in electrical motors are

the least studied of the deep level flow paths is an almost-trial rotating machine. Martinelli (44) has derived an expression for the heat transfer to a fluid flowing between two parallel plates with a constant heat rate at each plate. But that expression is valid only when the fluid is being symmetrically heated from each plate. In our case, the fluid is heated from one side and cooled from the other.

Moore (45) and Sieder (46) modified that expression of the Nusselt number for heat transfer across air-gap and compared this with other experimental data. His modified formula will be used in this study.

Now consider the concentric cylinder flow in which no axial flow occurs as shown in Fig. 4-3, which illustrates the basic structure of the motor for this thermal analysis. In this case, the flow is actuated only by the rotation of one of the cylinders and can be characterized by a Reynolds number and by a dimensionless curvature factor. The Reynolds number is defined in the usual way.

$$\begin{aligned} R_{\text{eq}} &= \frac{(\text{equivalent diameter})(\text{mean velocity})}{\text{kinetic viscosity}} \\ &= \frac{V_p D}{\nu} \end{aligned} \quad (4.23)$$

where

π = air-gap length

v_p = peripheral velocity and radius

The dimensionless Sieder's number for heat transfer across air-gap was derived to be (47)

Fig. 4-9 Heat flow of EC PM motor in normal structure

$$h_{eq} = \frac{F_g P_g R_g (a_g/2)^{3/4}}{10(P_g + 10(1+3P_g)) + 0.34a_{eq} (a_g/2)^{3/4} (1.26)} \quad (4.26)$$

where

L = friction factor

$L = 0.315$ when $Re_{eq} \leq 10,000$

P_g = Prandtl number

Re_{eq} = Reynolds number

σ_g = skin friction coefficient

The relation between skin friction coefficient and the Reynolds number approximated from the measured data is to be

$$\sigma_g = (165/Re_g)^{0.643} \quad (4.27)$$

The heat transfer coefficient by convection across air-gap is

$$h_g = \frac{Nu_g}{2\delta} \quad (4.28)$$

The power transfer by convection across air-gap is

$$P_{cgl} = h_g A_g \pi T_m = \pi_g \delta \quad (4.29)$$

The heat transfer across the air-gap by radiation is

$$P_{rad} = (5.67 \times 10^{-8} / (\pi_g + 10)) \delta = \pi_r \delta + 3734 \delta^2 / \pi_g \pi \quad (4.30)$$

The total heat transfer across the air-gap is the sum of these two heats,

$$\dot{Q}_a = \dot{Q}_{a1} + \dot{Q}_{a2}$$

4. Heat transfer from motor to ambient air (41). For convection in still air, the heat transfer coefficient can be used from (41), converted to the units used in this study

$$h = 14.46 \frac{(\rho_f - \rho_g)^{0.25}}{D_1^{0.25} T_{g1}^{0.25}} + 0.01618^{-0.4} \rho_{f1}^{0.713} D_1 \quad (4-11)$$

where

D_1 = equivalent diameter of motor

T_{g1} = air film temperature

$$= \frac{T_1 + T_2}{2} = 373$$

So the heat dissipation from the motor and the air by convection is

$$\dot{Q}_{a1} = hA_s(T_f - T_c) \quad (4-12)$$

And the heat dissipation by radiation is

$$\dot{Q}_{a2} = 5.73 \times 10^{-8} \times (0.75 + 0.71)^4 \times (T_f + 273)^4 A_s \quad (4-13)$$

The total heat transfer from the surface of the motor to the environmental air is then

$$T_Q = T_{cl} + T_{cd} \quad (4.30)$$

4.1. Temperature rise computation. When all above heat dissipation are computed, the temperature rise of structure winding, T_w , and field part, T_f , can be determined by solving the thermal differential equations.

$$\frac{dT_w}{dt} = (T_i - T_w)/\tau_w \quad (4.31)$$

$$\frac{dT_f}{dt} = (T_a - T_f)/\tau_f \quad (4.32)$$

These equations are the nonlinear differential equations; as the numerical method, Runge-Kutta predictor-corrector method [21] can solve these equations. The solvers for robotic applications have a short integration step cycle (Figure 111); as the temperature rise is computed on a one-hour time period, which is different from the continuous solving in general purpose solvers shown in Table 3-1.

4.1.2 Inside-out Algorithm

Since the basic structures of normal and "inside-out" are quite similar, this section will discuss just the differences between these two structures.

The thickness of the PM magnet in this structure of inside can be obtained using the same magnet circuit equation except for the difference of reluctances by the change of structure. The changed reluctances are armature and field yoke reluctances:

$$\beta_{xy} = \frac{r_{xy}}{r_x^2 \alpha^2 h_{xy}} \quad (4.17)$$

$$h_{xy} = \frac{r_{xy}}{r_x^2 \alpha^2 \beta_{xy}} \quad (4.18)$$

where

$$r_{xy} = r(2 + 2\beta_{xy} + \alpha_{xy}) = r_x / \alpha_p$$

$$h_{xy} = r_x \beta_{xy}$$

$$r_{xy} = \frac{r(2 + \alpha_{xy})}{2\alpha_p}$$

r_x = thickness of acetone gel

Using eq. (4.17) and eq. (4.18), the thickness of the acetone gel is expressed by the following equation

$$r_x = \frac{1.34(2\alpha_p + \alpha_{xy}) + 0.84h_{xy} + r_{xy} \{1 + \alpha_p \beta_{xy}\}}{2\alpha_p \beta_{xy} \alpha_{xy} - 2\beta_{xy}^2} \quad (4.19)$$

The weight objective function of this score is

$$W_1 = W_a = W_f \quad (4.20)$$

where

$$W_a = W_{ax} + W_{ay} + W_{az} + W_{ax}$$

$$W_{ax} = r_{ax} h_{ax} \alpha_{ax}$$

$$W_{ay} = \frac{r_{ay}^2 \alpha_{ay}^2}{4} \{ (2 + 2\beta_{ay} + \alpha_{ay})^2 - (2 + 2\beta_{ay})^2 \}$$

$$W_{az} = \frac{r_{az}^2 \alpha_{az}^2}{4} \{ (2 + 2\beta_{az})^2 - (2 + 2\beta_{az})^2 \} - \alpha_p r_{az} \alpha_{az} r_{ax} \alpha_{ax}$$

$$W_{ax} = r_{ax} \{ 2\beta_{ax} r_{ax} - h_{ax} \} r_{ay} \alpha_{ay}$$

the losses of this series are

$$P_{\text{loss}} = P_{\text{op}} + P_{\text{st}} \quad (4.41)$$

where

$$P_{\text{op}} = \omega^2 \frac{1}{2} N_{11} N_{22} N_{33} N$$

$$P_{\text{st}} = P_{\text{st}1} + P_{\text{st}2}$$

$$P_{\text{st}1} = P_{\text{st}} N_{11}$$

$$P_{\text{st}2} = P_{\text{st}} N_{22}$$

$N_{11}, N_{22}, P_{\text{st}}$ - same losses in teeth, yokes

The heat dissipation of this structure is different from that of a normal structure motor. The heat generation in the armature is dissipated to the field part and air with a larger surface area as the effective heat dissipation area is greatly increased (Fig. 4-38). As a result, the thermal equation can be changed as follows:

$$\frac{d\theta_a}{dt} = (P_1 + P_2 + P_3)/C_a \quad (4.42)$$

$$\frac{d\theta_f}{dt} = P_3/C_f$$

4.3. CONCLUSION

This study is concentrated on weight minimization ($\theta = 0$) because of the importance of weight in manipulator operation mentioned in Chapter I. Based on the design procedure illustrated in Fig. 4-6, the computer program is

Fig. 4-12 Heat dissipation of DC PM motor on "inside-out" structure

organized and the weight objective function is optimized using NBT and pattern search method. This design procedure will be explained using the structure of a computer program.

4.1.1. Computer Program

4.1.1.1. Main program

The main computer program will do the following tasks:

1. Determine the purpose of DC PM motor if the motor is for general purpose or for multilink manipulator.
2. Read in the input data and initial feasible values of design variables.
3. Find the magnetization and core loss curves of selected core material.
4. Control the NBT by the penalty factor
5. Check the temperature rise, adjust the current density, and repeat above procedures 2 and 4 until the temperature rise is the same as the limit.
6. Print the specifications of the designed motor.

4.1.1.2. Subprogram "PATTERN"

The subprogram "PATTERN" will find the minimum point by the following procedures:

1. The subprogram "EXPLORE" will find the descent direction by trying all the directions of design variables that can reduce the objective function. If the search could not reduce the objective

function, the new values of design are replaced by the former values before the search.

2. If the exploratory move fails, the search step distances will be reduced and the exploratory move tried until the desired direction is found.
3. The pattern move will be done by the subprogram "PATTERN." This subprogram will find the minimum point using a Fibonacci search which is an effective line search method.
4. The convergence criterion can be satisfied if the three successive results of pattern search are within a satisfactory limit, otherwise the above procedure will be reiterated until the criterion is satisfied.

3.3.1.3 Subprogram "PATTERN"

The objective function can be determined from this subprogram "PATTERN" which will find the performance parameters and check the constraints. The computing procedures are shown in Fig. 4-6. The detailed flow charts of optimization and computer program are in Appendices C and D.

3.3 Results of optimization

3.3.1 Convergence Check

The penalty function method and pattern search method used in this computer program of optimum design show rapid convergence to the optimum values. Figure 3-31 shows the

Fig. 4-12 Convergence results of optimization

convergence speed of optimum design of a 5 V-M motor. After six iterations, all of the design parameters are very close to optimum values, but the optimisation procedure is continued for up to 18 iterations to increase the accuracy of the results. Optimisation with different starting points was tried, and the results are within 0.2% difference.

4.3.2. Computer Output

The specifications of the designed motor are printed with the format shown below:

Result of optimisation

1. Input Data

Torque (N-m)	5.000
Number of poles	2
MAXIMUM speed (RPM)	1800
Power (W)	1.86

2. Design Parameters

Motor diameter (mm)	8.829
Motor length (mm)	2.372
Slot area (mm ²)	8.197
Stator width (mm)	8.864
Stator thickness (mm)	2.128
Current density (A/mm ²)	367.883
Ratio (L/W)	0.868

3. Electrical Specifications

Number of turns per slot	60
Number of slots per pole	20
Total number of turns	600

Diameter of armature coil (mm)	0.136
Resistance of armature coil (Ω)	1.749
Inductance of armature coil (mH)	28.479
Induced voltage (volts)	133.918

4. Magnetic Specifications

Flux (mWb)	0.00394
Flux density (TESLA)	
Magnet	0.818
Airgap	0.818
Armature teeth	1.800
Armature yoke	1.371
Field yoke	1.879

5. Loss (Watt)

Copper loss	108.883
Core loss	10.328
Mechanical loss	13.840
Total loss	133.051

Efficiency (%)	89.883
----------------	--------

6. Weight (kg)

Armature (MOTOR)	3.439
Winding	3.409
Yoke	1.010
Teeth	0.906
Field (GENERATOR)	2.347
Magnet	0.347
Yoke	2.079

	Total weight (including bearings)	2.781
7.	Acceleration (rad/sec ²)	502.147
	Torque (N-m)	0.493
	Inertia (kg-m ²)	0.0006
8.	Performance Constant	
	Voltage constant (Φ_B V-sec/rad)	0.349
	Torque constant (Φ_B N-m/A)	0.348
	Electrical time constant (msec)	21.596
	Mechanical time constant (msec)	41.815

4-3-3 Numerical Results with Different Torques

Table 4-3 shows the numerical results of optimum design of weight minimization ($\lambda = 2$) in a series of different torques. As lower torque ranges, the motor is very small, and it is hard to satisfy the following constraints with the small rotor diameter.

1. The width of slot in the armature is positive to get the armature winding in it.
2. The tooth width in the armature is positive and is larger than some value to make the magnetic flux density in the tooth less than saturation density.

As a result, the diameter of a rotor is to be increased to satisfy those constraints. As the torque becomes larger, those constraints can be satisfied easily with this diameter. When the torque of the motor is larger than 1 N-m (1.18 HP with 1875 RPM), the ratio remains constant.

Table 2. Regression of $\ln(\text{mean } \bar{y}_i)$ on $\ln(\text{mean } \bar{x}_i)$ in different regions

[illegible]

4.3.4 Comparison with Different Material and Structure

The DC PM motor is designed in different magnet materials, ferrite and SmCo_5 , and in different structures, normal and "inside-out." The results of these designs are illustrated in Table 4-6. From this table, one can see the following differences.

1. In normal structure, the SmCo_5 motor shows 30% less weight, 15 higher efficiency, and 10% higher no load acceleration than does the ferrite motor.
2. The SmCo_5 PM motor with "inside-out" structure has 200% increase of no load acceleration over the normal structure of a SmCo_5 motor. As a result, more motor torque can be delivered to the load.

4.4 Conclusions

Based upon the analysis and results of DC PM motor optimum design, we can get the following conclusions:

1. The DC PM motor has better characteristics than the wound motor, as shown in Table 4-6.
2. The DC PM motor has a unique shape, but the constraints modify the shape to make a feasible design.
3. The most desirable material for an actuator in robotic application is a rare earth PM material.
4. The suggested structure of a motor for robotic applications is the "inside-out" structure with a rare earth PM magnet.

3. The structure of optimum design is developed based upon the requirements of a Type I design. (page 49).

CHAPTER V
DESIGN OF DC PM MOTOR
FOR THE ENHANCED TIME OF OPERATION

Previously, the structure of electric motor design was presented applicable to the case when the working machine to be equipped by a motor was already designed or existed. Now we will consider an important case when the design of the motor and the machine can be done simultaneously:

Based on the results of optimum design of a DC PM motor in Chapter IV, the structure of design will be modified to satisfy the requirements of enhanced time of operation. The time of operation can be reduced by two different ways: matching the load and actuator, and optimizing the velocity trajectory via proper design of a control system. This study will be focused on the time reduction by matching the load and actuator conditions, promising a possibility to provide a simultaneous design of mechanical and electrical parts.

We assume that the minimum time velocity trajectory is obtained (which is known to be a triangle [19]), and the load parameters such as load inertia, J_L , angular displacement, ϕ_L , are given as input information. The design variables of this system will be motor torque, T_m , and gear ratio. Under given torque, the inertia is determined from the optimum design of motor for minimum weight. The

optimization of limiting motor torque and gear ratio will reduce the operation time. If the weight of motor is to be minimized under each different value of motor torque, then this time reduction will require a big computer program and will take much computing time. However, if the motor inertia can be expressed as a function of motor torque from the result of weight minimization, then that problem will become much simpler. Thus, the hierarchical design structure of time minimization in actuator system is organized as shown in Fig. 5-4.

When the velocity trajectory and input parameters are given, the time of operation can be reduced as follows.

- 1:- Find the functional relationship between the motor inertia and torque-
- 2:- Find the motor torque and gear ratio that can reduce the operation time and can satisfy the maximum bending rigidity of the weakest part-
- 3:- Compute the maximum speed and maximum power P_m that gives velocity trajectory
- 4:- Since the operating voltage is a function of magnetic flux that is determined in weight minimization, speed which was computed in step 3, and number of parallel paths in armature winding, the selection of terminal voltage will decide the diameter and the number of turns of armature winding-

Fig. 5-1. Design structure of motor for rotation system

1. To determine the motor performance parameters, the following procedures are required:
 - a. Compute the diameter of armature winding.
 - b. Compute the number of turns, current, resistance, and inductance of armature winding.
 - c. Compute the voltage constant and torque constant.
2. The computed parameters of motor inertia, armature resistance, armature inductance, voltage constant, torque constant, and damping coefficient will be used as input parameters for the design of a control system which is out of the scope of this dissertation.

3.1 Formulation of Optimum Time Requirements

3.1.1 Objective Function

We consider a single motor actuating the first or the second joint of a multi-actuator system. We presume that for the goals of this research, all parameters of the system may be averaged. Weight misallocation of the actuator at each link will have substantial effect, since the accelerating masses will be reduced correspondingly. Thus, minimizing the weight and time of operation for a single motor should lead to a substantial improvement in productivity for the whole manipulator.

Consider the motion of single joint of actuator-load assembly as shown in Fig. 3-3. There are two basic

a. BENDING ARM MOTION

b. WIST MOTION

Fig. 9-2 Schematic diagram of electric drive system

motion in this single joint--revolving arm motion and wrist motion. To move the manipulator arm with load, the motor torque will cope with the weight of the arm, weight of the load, and acceleration of load and manipulator. The joint system will be formulated with a rigid body structure, and the loading capacity of gear teeth will limit the applied motor torque.

According to the D'Alembert's principle, the mechanism must be in equilibrium under the influence of the external and internal forces, so the following torque equilibrium equations can be obtained.

$$\tau_1 = J_1 \ddot{\theta}_1 + B_1 \dot{\theta}_1 + \tau_w \quad (5.13)$$

$$\tau_w = J_w \ddot{\theta}_w + B_w \dot{\theta}_w + \tau_2^* \quad (5.14)$$

where

τ_1 = load torque at load side

τ_w = gravity torque of manipulator

$$= \bar{W}_L L \cos \theta \quad (\text{in wrist motion } \tau_w = 0) \quad (5.15)$$

\bar{W}_L = weight of manipulator

L = length of manipulator

τ_2^* = load torque at motor side

$$= (J_2 \ddot{\theta}_w + B_2 \dot{\theta}_w) / \gamma_{21}^2 + \tau_w / \gamma_{21} \quad (5.16)$$

J_1 = load inertia including manipulator inertia

J_w = motor inertia

B_w = damping coefficient at motor side

B_1 = damping coefficient at load side

ϕ_m = angular displacement at motor side

ϕ_l = angular displacement at load side

ϕ_g = gear ratio

From eq. (2.2) and eq. (3.4), we can get the following expression.

$$\tau_m = J_{\text{eff}} \ddot{\phi}_m + B_{\text{eff}} \dot{\phi}_m + \tau_g / \phi_g \quad (3.5)$$

where

$$\begin{aligned} J_{\text{eff}} &= \text{effective inertia at motor side} \\ &= J_m + J_l / \phi_g^2 \end{aligned}$$

$$\begin{aligned} B_{\text{eff}} &= \text{effective damping coefficient} \\ &= B_m + B_l / \phi_g^2 \end{aligned}$$

If we assume that this system is operating from a limited source of power and it is desired to have the system change from one state to another in minimum time, then it is necessary at all times to utilize all the power available, that is to use "bang-bang" control [18]. As a result of this control, the magnitudes of accelerations and decelerations are constant and extreme values, which will make the velocity trajectory trapezoidal. From the trapezoidal velocity trajectory, the acceleration torque, damping torque, load torque, and motor torque can be determined as in Fig 5-3. As can be seen from this figure, the motor torque which is the sum of acceleration torque, damping torque, and gravity torque as with a simple shape, it is a function of

Fig. 8-3 Graphical representation of motor target in a single joint system

angular displacement, speed, and acceleration. When we use the average torque, the analysis will become much simpler.

Combining eq. (3.4) and integrating yield

$$\int_0^t T_{\text{net}} \omega dt = \int_0^t T_m \omega dt = \int_0^t T_{\text{net}} \omega dt = \int_0^t T_m / \omega dt \quad (3.5)$$

where

ω = angular acceleration

The integration of motor torque will be simplified using the average rated torque, T_m .

$$\int_0^t T_m \omega dt = T_m T_r \quad (3.7)$$

And the integration of gravity torque can be determined using the series expansion of cosine term

$$\begin{aligned} \int_0^t T_g / \omega dt &= \frac{1}{\omega_r} \int_0^t T_g \cdot \cos \left(\frac{\pi}{2} \frac{t}{T_r} \right) dt \\ &= \frac{8 T_g T_r}{\pi^2} \left(1 - \frac{(\pi/2)^2}{16} + \frac{(\pi/2)^4}{256} \right. \\ &\quad \left. - \frac{(\pi/2)^6}{1344} + \dots \right) \end{aligned} \quad (3.8)$$

The average load torque is defined as

$$T_{\text{load}} = T_{\text{avg}} / \omega_r = \frac{1}{\omega_r} \int_0^t T_g \omega dt$$

$$= \frac{15}{8} \frac{1}{\tau_0} = \frac{(15/2)\tau_0^2}{10} = \frac{(15/2)\tau_0^2}{120} = \frac{(15/2)\tau_0^2}{60\tau_0} = \tau_0 \quad (3.9)$$

Substituting eq. (3.7) + eq. (3.8) into eq. (3.4) yields

$$\begin{aligned} J_{eff}a_n &= \tau_0 a_n + \frac{a_n^2}{2} \tau_{eff} + \tau_{damp} a_n \\ \tau_0 &= \tau_{damp} + \tau_n^2 = \frac{\tau_0 a_n \tau_{eff} a_n}{2} + \tau_0 a_n J_{eff} = 0 \end{aligned} \quad (3.10)$$

The acceleration time can be determined by solving the quadratic equation of eq. (3.10).

$$\tau_n = \frac{\tau_0 a_n \tau_{eff} + \sqrt{4\tau_0^2 a_n^2 \tau_{eff}^2 + 4\tau_0 a_n \tau_{eff} (\tau_0 - \tau_{damp})}}{2(\tau_0 - \tau_{damp})} \quad (3.11)$$

The spin-down time is two times the acceleration time as can be seen from the symmetric triangular velocity impulse (Fig. 1).

$$t_n = 2\tau_n \quad (3.12)$$

In the stick motion, the gravity torque is zero, so eq. (3.1) becomes

$$\int_0^{\tau_n} J_{eff} \dot{\omega} dt = \int_0^{\tau_n} \tau_n \dot{\omega} dt = \int_0^{\tau_n} \tau_n d\omega \quad (3.13)$$

and the integration of damping torque is

$$\begin{aligned}
 T_b &= \int_0^{T_a} \sigma_{act} \pi dt \\
 &= \frac{\pi \sigma_{act} (T_a^2)}{2}
 \end{aligned}
 \quad (5.13)$$

Substituting eq. (5.6) and eq. (5.14) into eq. (5.12) yields the following operating time:

$$t_p = \frac{\pi \sigma_{act} (T_a^2)}{2} + \frac{\sqrt{[2 \sigma_{act} (T_a^2)]^2 + 16 J^2 \sigma_{act}^2 T_a}}{2 \sigma_{act}} \quad (5.14)$$

The objective function for raising arm motion and wheel motion are formulated as eq. (5.12) and eq. (5.15). The constraint in this time reduction problem is the bending limit of gear tooth. In this study, the spur gear will be used for the computation of gear bending capacity.

3.1.1. Bending Capacity of Spur Gear Teeth (II)

In the gear raising, the number of pairs of gear teeth in contact simultaneously varies from one to two or more. However, the largest limit can be determined by assuming the most unfavorable conditions.

Consider the ability of a single tooth to carry bending load almost at the end of tooth as shown in Fig. 3-4. When the force F is applied at point A, the tangential component of F will produce a bending moment $F_b l$ at the base of the tooth. If we assume that the tooth is a cantilever beam, the bending limit of gear tooth will be determined as follows. The stress of a beam can be expressed as

Fig. 9-4 Bending capacity of a gear system

$$\sigma = \frac{dF_b l}{b h^2} = \frac{F_b}{b} \frac{l}{h^2} \quad (8.16)$$

where

b = thickness of tooth in axial direction

h = width of tooth

l = height of tooth

The factor l^2/hl is a purely geometrical property of the size and shape of the tooth and may be written as a function of the circular pitch. The bending limit force of gear tooth will be expressed as

$$F_b = b \sigma y \quad (8.17)$$

where

$y = l^2/(6bh) =$ Lewis factor

$p =$ circular pitch $= \pi/P_d$

$P_d =$ diametrical pitch

$=$ number of teeth per inch (2.54 cm) of pitch diameter

Here, y is a pure number and is called Lewis factor which depends on the number of teeth in the gear and system of gearing used. The limit torque that can be applied to the gear tooth will be computed as

$$T_{\text{lim}} = F_b r$$

When the gear material, diametral pitch, and diameter of pitch circle are given, the bending capacity can be computed.

5.2 Time Reduction

Based on the procedure of time reduction illustrated in Fig. 5-1, the detailed analysis in each step will be discussed.

5.2.1 Functional Relationship

The functional relationships between inertia and torque can be obtained from the result of weight optimization in Chapter IV. The relations can be approximated using linear regression of the *msa* package.

1. Normal structure of motor

$$J_m = 0.0027T_f^{1.1916}$$

2. "Inside-out" structure of motor

$$J_m = 0.4001T_f^{1.2166}$$

These relations express the dependencies between the parameters when the motor is in optimum configuration with respect to minimum weight in normal and "inside-out" structure.

Figure 5-3 shows the actual data and approximated data of inertia with different values of torque, which are quite close to each other.

Fig. 8-8 Approximation of inertia as a function of rotor length and actual data from the result of weight minimization

3.2.2 Computation of T_x and a_x

Now the time minimization problem in raising arm motion is set as follows.

Minimize

$$T_x = \frac{m_x g L_x + \sqrt{(m_x g L_x + \frac{1}{2} m_x L_x^2 \omega^2)^2 + (m_x g L_x + \frac{1}{2} m_x L_x^2 \omega^2)^2 (T_c^2 - T_{c, \text{avg}}^2)}}{2(T_x - \frac{1}{2} m_x L_x \omega^2)} \quad (3.18)$$

subject to maximum bending limit of gear teeth.

We will assume that the effective damping coefficient is zero; thus eq. (3.18) of raising arm motion will be simplified as follows

$$\text{Minimize } T_x = \frac{2 \sqrt{(m_x g L_x + \frac{1}{2} m_x L_x^2 \omega^2)^2 (T_c^2 - T_{c, \text{avg}}^2)}}{T_x - \frac{1}{2} m_x L_x \omega^2} \quad (3.19)$$

subject to maximum bending limit

Among the variables in eq. (3.19), the load angular displacement and load inertia are given as input parameters. The parameter data for the PUMA robot, Unimation 500, are listed in Table 3-1. The motor inertia, J_m , was expressed as a function of motor torque.

When the constraint is not applied to this problem to see the general trend of time function, then the time function of eq. (3.19) can be plotted in three dimensions with motor torque and gear ratio as variables as Fig. 3-5. As can be seen from this figure, the operation time of the manipulator is reduced as the motor torque becomes larger.

TABLE 3-1 Parameter data for robot, URIMATE 300

Load conditions		Spring constants
Arm weight (kg)	m_2	34.98
Arm length (m)	l_2	0.433
Load inertia (kgm^2)	J_1	10.48
Angular displacement (rad.)	θ_1	0.70

Fig. 3-4 Operation time function vs. gear ratio (q_g) and motor torque (T_g)

In a given motor torque, the optimum gear ratio can be found to have minimum operation time from this figure. The optimum gear ratio can be determined analytically as

$$\frac{T_h}{T_{h0}} = 1 + \gamma_c = \sqrt{\frac{T_{h0}^2}{T_c^2} + \left(\frac{T_{h0}^2}{T_c^2}\right)^2} + \frac{1}{\gamma_m} \quad (5.24)$$

So when the gear ratio in each motor torque is determined, then the operation time of raising arm action can be drawn as shown in Fig. 5-7. We can see from this figure that the operation time of the manipulator using the "inside-out" structure motor is 13% less than the manipulator using normal structure motor. When the maximum bending limit constraint is applied by these figures, the maximum available torque is the optimum torque and the gear ratio will be computed successfully.

From eq. (5.22) and eq. (5.24), the bending limit torque can be computed with different values of diametral pitch and diameter of pitch circle as shown in Fig. 5-8. When the diametral pitch of the gear $P_d = 16$ and the diameter of the pitch circle $D_{pd} = 1.5$ inches (4.88 cm), the limit torque is determined from Fig. 5-8 to be 1.63 N-m. The operation time is determined from Fig. 5-7 to be 4.8 sec using normal structure of motor and 3.7% sec with "inside-out" structure of motor.

Fig. 1-7 Operation time vs. motor torque

Fig. 3-8 Limit torque vs. geometrical pitch (P_g) for different diameters of patch diameter (D_p)

3.2.3 Motor Performance Targets

The performance parameters of the motor will be determined by the following procedures:

1. When the operation time is determined, the minimum speed and maximum power will be computed respectively as

$$v_m = \frac{2\pi n_p \omega_b}{k_p} \quad (3.21)$$

$$P_m = v_f v_m$$

2. If the nominal voltage is selected, then the diameter of winding that can deliver maximum power, the number of turns, current, resistance, and inductance (32) of armature winding can be computed as

$$d_w = \sqrt{\frac{4 \pi^2 n_p^2 \omega_b^2 + k_p^2 P_m^2}{\pi^2 d_p^2}} \quad (3.22)$$

$$N = \pi d_w \text{Integer} \left(\frac{k_p}{\pi d_w^2} \right) \quad (3.23)$$

$$I = \frac{P_m k_p \omega_b}{(\pi d_w^2 N)^2} \quad (3.24)$$

$$L_w = \frac{(\pi d_w)^2 N^2 \mu_0 \mu_r \omega_b^2 / (2\pi)^3 d_p^2}{4 \pi d_w} \quad (3.25)$$

1. The voltage constant, E_{av} , and torque constant, K_{av} , will be computed as

$$E_{\text{av}} = \frac{81.5}{75} \quad (3.27)$$

$$K_{\text{av}} = \frac{R_{\text{I}}}{E_{\text{av}}} \quad (3.28)$$

3.3 Numerical Example

Using the Minolta 150, the design of a DC PM motor in a single point motion is computed by these procedures with a result shown in Table 3-3. The "inside-out" structure motor has better characteristics in all areas:

3.4 Conclusions

Based on the analysis and the results of DC PM motor design for minimum time of operation, the following conclusions can be obtained:

1. The operation time is reduced by matching the load and the actuator conditions with minimum bending capacity of gear teeth, and the problem minimizing the weight and reducing the time of operation is solved via hierarchical design.
2. The operation time of raising and motion using "inside-out" structure of motor is 40% less than that with normal structure of motor.

CHAPTER VI MOTOR DESIGN PROPERTIES, CONCLUSIONS AND FUTURE WORK

Based upon the results of analyses in this dissertation, this chapter will recommend the design structure of a motor for a multilink manipulator. The conclusions of this work are presented and suggestions for future work are discussed.

6.1 Design Structure

Figure 6-1 describes the structure of motor design for the actuators in a multilink manipulator. Actually, this design structure is the integration of discussions in Chapters IV and V. In other words, the operation time is reduced to find the most suitable motor torque after the first step optimization of motor design is finished. This first step design determines the values of main design variables. When the time reduction is finished, then the second step of motor design is done to find the detailed motor parameters and performance parameters such as diameter, current, number of turns in the armature winding, resistance and inductance of armature winding, and voltage and torque constant. The damping coefficient is hard to compute, so this may be obtained from measurements or from similar machines.

Fig. 8-1. - continued

8.1 Conclusions

The following conclusions may be obtained from this dissertation:

1. The study of the state of the art in motor design leads to the hierarchical optimum design structure which divides the optimization problem into several suboptimization problems. This decoupled optimization will simplify the design noticeably and has the advantage of flexibility; detailed designs that may be different from different purposes can be done using the same main program.
2. The notion "optimum configuration" is introduced which is defined as the length/diameter ratio leading to the minimization of the weight of the motor or maximization of its efficiency. The optimum configuration is computed theoretically for a number of motors. It is found that not all of the industrially manufactured motors satisfy the criterion of optimum configuration.
3. From the database we found that the 04 H motor has the highest V/Φ ratio among any other type of motor as shown in Table 8-1, and the best configuration as DC PM motor manufactured in industry is determined for the best V/Φ ratios or maximum efficiency as shown in Table 8-1.

Table 4-1 Comparison of T/90 ratio between different types of motor

Type	T/90 ratio			
	CL1	CL2	CL3	CL4
PM	0.034	0.345	0.319	0.401
Series	0.034	0.318	0.279	-
Shunt	0.034	0.271	-	0.387
Series-aid	0.018	0.213	0.264	0.303
Synchrosator	0.038	0.215	-	-

Table 4-2 Comparison of optimum configurations

Criteria	Theory	Database
Maximum weight	0.85	0.3
Maximum efficiency	1.54	0.8

4. Most of the machines are proven to have their optimum configurations which may be different for different purposes, and the optimum configuration in weight minimization is not changed although the power rating is changed.
5. The result of optimum design of the DC PM motor shows that the DC PM motor has much better characteristics than the wound motor, and that the most desirable motor for the robotic applications or for the automated manufacturing system will be the DC PM "inside-out" motor with SMCs which will upgrade the performance characteristics while maintaining the technical requirements of the actuator.
6. The operation time is reduced by matching load and actuator conditions and the hierarchical structure of motor design is especially necessary to simplify the problems of multiple-goal optimization and to reduce the computing time.
7. The interactive computer programming that consists of 1200 lines of Fortran codes using the nonlinear programming algorithms, pattern search and Fibonacci search, can be applied to any other types of machine by just modifying the subprogram, "DESIGN," which differs for different types of motors.
8. The result of optimum motor design can be applied to the actual manufacturing of the motor and will improve the motor cost, effectiveness and other

characteristics while decreasing the productivity of robotic applications.

4.3 SUGGESTIONS FOR FUTURE RESEARCH

1. In the analysis of the database, the dimensions of the motor are the outside case dimensions which are proportional to the rotor dimensions. If the exact rotor dimensions can be obtained from the industry, we can suggest a more accurate optimum configuration of the motor for maximum weight and maximum efficiency.
2. If the motor is actually manufactured from the results of optimum design and all the performance parameters and temperature rise are measured from this manufactured motor, the optimum design of the motor can be further improved by comparing the computed parameter with the measured parameters.
3. The operation time was reduced by matching the load and starter conditions with the concept of an average torque. The exact analysis of load and motor torques will provide more accurate results.

APPENDIX A TRANSFORMER

Figure 4-1 shows the simplified geometry of a core transformer. If the flux varies sinusoidally with time the primary and secondary induced voltages are

$$E_1 = 4.44 B_m f N_1 \quad (A.1)$$

where

E_1 , E_2 = the primary and secondary voltages

N_1 , N_2 = number of primary and secondary windings

f = frequency of power source

B_m = peak value of magnetic flux

The window area which is the winding area of transformer is assumed to be divided equally between primary and secondary windings, therefore the total number of turns in the primary winding can be determined as

$$N_1 = \frac{20.1 B_m^{-1} \cdot 0.16}{(\pi D_w^2/4)} \quad (A.2)$$

where

k_w = window utilization factor

D_w = diameter of wire

In order to calculate the current in any winding, we considered the current density at first. The losses of a transformer is proportional to the cube of geometrical dimension and the square of current density [7].

$$P_{\text{loss}} = K_2 J_2^2 \quad (A.3)$$

The area product which is an important variable for relating the power losses, the dimensions, and the number of windings, can be expressed as,

$$\begin{aligned} A_p &= (\text{winding area}) \times (\text{cross section area}) \\ &= L_w a_w^2 (B_w - 0.01) / 2 \end{aligned} \quad (A.4)$$

Then the losses can be expressed as,

$$P_{\text{loss}} = K' A_p^{-2/3} J_2^2 \quad (A.5)$$

The average temperature increase of a transformer winding is proportional to the energy losses and inversely proportional to the surface area of transformer. As a result the temperature rise may be written as,

$$\Delta T = \frac{K_3 A_p^{-2/3} J_2^2}{K_4 A_p^{2/3}} \quad (A.6)$$

Thus at a given temperature rise the current density is expressed as a function of area product,

$$J = K_5 \left[\frac{1}{L_w a_w^2 (B_w - 0.01)} \right]^{0.125} \quad (A.7)$$

The induced output volt-ampere(VA) is given by

$$\begin{aligned} (VA) &= E_p J_2 = 4.44 f_m B_w^2 a_w l_p \\ &= K_6^{0.875} (B_w - 0.01)^{0.875} B_w^{1.75} \end{aligned} \quad (A.8)$$

where

$$K = 1.42 \times 10^6 f_m^2 K_5$$

and the length of transformer can be determined as follows: Mean turn length of each winding is

$$R_{12} = \pi (R_g + R_g) \quad (8.10)$$

The total length is primary and secondary windings becomes

$$\begin{aligned} L_1 &= R_{12} N \\ &= \frac{2\pi R_g^2 (R_g + R_g) (N_g + N_g)}{(R_g^2/4)} \end{aligned} \quad (8.11)$$

Resistance of each winding is then

$$R = \frac{4\pi R_g (R_g + R_g) (R_g + R_g) N_g}{(R_g^2/4)} \quad (8.12)$$

And the copper losses in each winding can be expressed as

$$L_{cp} = \frac{R_g (R_g + R_g) (R_g + R_g)^2 (N_g + N_g)^2 I_g^2}{(R_g^2/4)} \quad (8.13)$$

Thus the maximum magnetic flux density as decided we can assume that the core losses per unit weight are constant.

$$L_{cp} = L_{cp}^* M_{12} \quad (8.14)$$

where

$$L_{cp}^* = \text{core losses per unit weight}$$

APPENDIX B INTERCHANGE NOTES WITH FM AFTER

When the permanent magnet is used as a field excitation source as in Fig. B-5, the advantages of the FM become not applicable in field computation for this kind of structure. Therefore an accurate mathematical model in field determination must be employed to take all the parameters into account. When the rotor is operated at synchronous speed there are no free currents inside the rotor. As a result, the flux pattern in a steady state is not changed, which enables us to solve the Laplace equation.

The governing equations for this case are

$$\nabla \cdot \vec{B} = 0 \quad (B-1)$$

$$\nabla \times \vec{B} = 0 \quad (B-2)$$

Because the curl of \vec{B} is zero, a scalar magnetic potential can be defined as,

$$\vec{B} = -\nabla \psi \quad (B-3)$$

From equations (B-1) and (B-3) with $\vec{B} = \mu \vec{H}$, the magnetic scalar potential obeys the Laplace equation

$$\nabla^2 \psi = 0 \quad (B-4)$$

In this analysis the variation of scalar potential along the x -axis is neglected. And if only the fundamental component of harmonics of winding current is considered, the three phase windings approximates a surface current distribution of the form

$$\vec{J}(x,t) = Re \{ \vec{J}_0 e^{j(\omega t - \alpha x)} \} \hat{z} \quad (8.10)$$

where

$$\vec{J}_0 = m_{sp} \vec{I}_a$$

m = number of pole pairs

The magnetic potential within the stator is then also sinusoidally varying with time.

$$\vec{r}(x,t) = Re \{ \vec{r}(x) e^{j(\omega t - \alpha x)} \} \quad (8.11)$$

Substituting eq.(8.10) into eq.(8.11) with cylindrical coordinates yields

$$\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial \vec{r}(r)}{\partial r} \right) = \frac{\partial^2}{\partial x^2} \vec{r}(x) = 0 \quad (8.12)$$

The magnetic scalar potential in different regions such as rotor, airgap, stator, and outside the stator can be expressed accordingly

$$1. \text{ Rotor} \quad \vec{r}_1(x) = \vec{A}_1 e^{\alpha x} \quad | \quad x < x_1 \quad (8.13)$$

$$2. \text{ Airgap: } \vec{B}_2(r) = B_2 r^B + B_2' r^B \quad ; \quad a_2 < r < a_3 \quad (B.17)$$

$$3. \text{ Stator: } \vec{B}_3(r) = B_3 r^B + B_3' r^B \quad ; \quad a_3 < r < a_4 \quad (B.18)$$

$$4. \text{ Subside: } \vec{B}_4(r) = B_4' r^B \quad ; \quad r > a_4 \quad (B.19)$$

The above magnetic vector potential in different regions can be obtained from eq.(B.11)-eq.(B.13) by applying the boundary conditions at each point as follows:

$$1. \quad r = a_1 \quad ; \quad B_{1r} = B_2 \quad , \quad B_{1\theta} = B_{2\theta} \quad (B.11)$$

$$2. \quad r = a_2 \quad ; \quad B_{2r} = B_{1r} = B_2 \quad , \quad B_{2\theta} = B_{1\theta} \quad (B.12)$$

$$3. \quad r = a_3 \quad ; \quad B_{3r} = B_{2r} \quad , \quad B_{3\theta} = B_{2\theta} \quad (B.13)$$

The magnetic vector potential at each region is:

$$v_1(x, y, z) = (B_1 B_2 r^B + B_1' B_2' r^B) e^{j(\omega t - \theta_1)} \quad (B.14)$$

$$v_2(x, y, z) = [B_2 (B_2 r^B + \frac{B_2}{r^B}) + B_2' (B_2' r^B + \frac{B_2'}{r^B})] e^{j(\omega t - \theta_2)} \quad (B.15)$$

$$v_3(x, y, z) = [B_3 (B_3 r^B + \frac{B_3}{r^B}) + B_3' (B_3' r^B + \frac{B_3'}{r^B})] e^{j(\omega t - \theta_3)} \quad (B.16)$$

$$v_4(x, y, z) = (B_4 B_4' r^B + B_4' B_4' B_4' r^B) e^{j(\omega t - \theta_4)} \quad (B.17)$$

The magnetic field in each region can be obtained from the gradient of magnetic vector potential as in next page:

$$\begin{aligned} \mathcal{H}_1 = & \left[\mathcal{H}_1^* \mathcal{H}_2^* \pi r^{2m-1} \{ \sin(\omega t - \omega_0) - \mathcal{H}_1^* \pi r^{2m-1} \cos(\omega t - \omega_0) - i \} \right] \mathcal{H}_1 \\ & + \left[-\pi r^{2m-1} \mathcal{H}_1^* \mathcal{H}_2^* \cos(\omega t - \omega_0) - \mathcal{H}_1^* \pi r^{2m-1} \sin(\omega t - \omega_0) - i \right] \mathcal{H}_2 \end{aligned} \quad (21.11)$$

$$\begin{aligned} \mathcal{H}_2 = & \left[\pi \{ \mathcal{H}_2^* r^{2m-1} - \frac{\mathcal{H}_2}{r^{2m-1}} \} \mathcal{H}_3 \sin(\omega t - \omega_0) - \pi \{ \mathcal{H}_2^* r^{2m-1} - \frac{\mathcal{H}_2}{r^{2m-1}} \} \cos(\omega t - \omega_0) - i \right] \mathcal{H}_1 \\ & + \left[-\pi \{ \mathcal{H}_2^* r^{2m-1} + \frac{\mathcal{H}_2}{r^{2m-1}} \} \mathcal{H}_3 \cos(\omega t - \omega_0) - \pi \{ \mathcal{H}_2^* r^{2m-1} + \frac{\mathcal{H}_2}{r^{2m-1}} \} \sin(\omega t - \omega_0) - i \right] \mathcal{H}_2 \end{aligned} \quad (21.12)$$

$$\begin{aligned} \mathcal{H}_3 = & \left[\pi \{ \mathcal{H}_3^* r^{2m-1} - \frac{\mathcal{H}_3}{r^{2m-1}} \} \mathcal{H}_4 \sin(\omega t - \omega_0) - \pi \{ \mathcal{H}_3^* r^{2m-1} - \frac{\mathcal{H}_3}{r^{2m-1}} \} \cos(\omega t - \omega_0) - i \right] \mathcal{H}_1 \\ & + \left[-\pi \{ \mathcal{H}_3^* r^{2m-1} + \frac{\mathcal{H}_3}{r^{2m-1}} \} \mathcal{H}_4 \cos(\omega t - \omega_0) - \pi \{ \mathcal{H}_3^* r^{2m-1} + \frac{\mathcal{H}_3}{r^{2m-1}} \} \sin(\omega t - \omega_0) - i \right] \mathcal{H}_2 \end{aligned} \quad (21.13)$$

$$\begin{aligned} \mathcal{H}_4 = & \left[-\frac{\mathcal{H}_4 \mathcal{H}_1}{r^{2m-1}} \sin(\omega t - \omega_0) + \frac{\mathcal{H}_4 \mathcal{H}_2}{r^{2m-1}} \cos(\omega t - \omega_0) - i \right] \mathcal{H}_1 \\ & + \pi \left[-\frac{\mathcal{H}_4}{r^{2m-1}} \mathcal{H}_2 \cos(\omega t - \omega_0) - \frac{\mathcal{H}_4}{r^{2m-1}} \sin(\omega t - \omega_0) - i \right] \mathcal{H}_2 \end{aligned} \quad (21.14)$$

The expressions of $\mathcal{H}_1^* - \mathcal{H}_2^*$ and $\mathcal{H}_3^* - \mathcal{H}_4^*$ are as follows: The order of variables is not in matrix order because the derivations can start from different variables

$$\mathcal{H}_1^* = \frac{\mathcal{V}_1}{\mathcal{K}_1^2 \mathcal{V}_1 + \mathcal{H}_2}$$

$$\mathcal{H}_2^* = -\frac{\mathcal{H}_1 \mathcal{H}_1}{\mathcal{K}_1^2 \mathcal{V}_1 + \mathcal{V}_2}$$

$$\mathcal{H}_3^* = \mathcal{K}_2^2 \mathcal{H}_1$$

$$\mathcal{H}_4^* = \mathcal{H}_2^* \mathcal{H}_2^* = \mathcal{H}_2^2$$

$$x_1 = x_2 + x_2^2/a_1^{2n}$$

$$x_1^2 = x_2^2 + x_2^2/a_1^{2n}$$

$$x_2 = 2 \cdot a_1^2 \left[a_2^{2n} a_2 (1 + a_2/a) + (1 + a_2/a) x_2 + a_2^{2n-1}/a \right]$$

$$x_2^2 = 4 \cdot a_1^4 \left[a_2^{2n} x_2^2 (1 + a_2/a) + (1 + a_2/a) x_2^2 \right]$$

$$x_4 = x_2 x_1^2$$

$$x_4^2 = x_2^2 x_1^2$$

$$x_8 = a_2^{2n} x_4 + x_2$$

$$x_8^2 = a_2^{2n} x_4^2 + x_2^2$$

where

$$x_2^2 = (a^2 - a_2) / (a^2 - a_2) a_2^{2n}$$

$$x_2^2 = a_2 a_2^2 (1 + a_2/a) a_2^{2n-1}$$

$$x_2^2 = -(1 + a_2) / (a^2 - a_2) a_2^{2n}$$

$$x_1 = \frac{1 + a_2/a}{a_2^{2n}} = x_1^2 (1 + a_2/a)$$

$$r_2 = \frac{1}{a_2^2 b_2} \left[\frac{1}{a_2^2 b_2} - v_2^2 (1 + v_2 a_2^2) \right]$$

$$v_2 = \frac{1}{a_2 b_2} \left(\frac{1}{a_2^2} - 1 + v_2^2 a_2^2 \right)$$

$$a_2 = a_1/2$$

$$a_2 = a_1 = 0$$

$$a_2 = a_1 = 0$$

Among these magnetic fields only the radial component of magnetic field in the stator, $B_{\theta 2}$, and the tangential component of magnetic field in the rotor are of interest to us. The magnetic flux in the stator is obtained from the integration,

$$\begin{aligned} \Phi_{2s} &= \int_{\theta_1}^{\theta_2} B_{\theta 2} \, d\theta \, dL \\ &= L \int_{\theta_1}^{\theta_2} \left(\frac{1}{2} (a_2^2 - 1/a_2^2) - x_2^2 (a_2^2 - a_2^2) - B_2 \cos(\theta_2 - \theta) \right) \\ &\quad + B_2^2 \left(\frac{1}{2} (a_2^2 - 1/a_2^2) - B_2^2 (a_2^2 - a_2^2) \right) \sin(\theta_2 - \theta) \, d\theta \end{aligned} \quad (8.23)$$

The magnetic flux linkage that is cut by the stator winding coil is

$$\lambda_2 = \frac{N_2 \Phi_{2s}}{2} = \frac{N_2}{2} (x_2^2 / r^2 - B_2^2) \cos \theta \quad (8.24)$$

The average torque on the ring is

$$T = \frac{2k_1 k_2 \omega_m}{\pi} (x_j - x_j^R) \cos \delta \quad (8.15)$$

The torque exerted on the PM ring becomes

$$T = -2k_1 k_2 \omega_m (x_j^R - x_j^S) \sin \delta \quad (8.16)$$

The pole pair torque and the average torque of a three phase p pole pair motor are then

$$T_{p,av} = \frac{2k_1 k_2 \omega_m}{\pi} L_N (x_j - x_j^R) \pi \quad (8.17)$$

$$T_{av} = -p_s L_N \pi (x_j^R - x_j^S) \sin \delta \quad (8.18)$$

When the number of pole is selected the angular speed of rotor in a synchronous motor is determined and the average output power can be computed accordingly as,

$$P_{av} = T_{av} \omega \quad (8.19)$$

APPENDIX B
FLAM GRAPH OF COMPUTER Programs

For the installation of this operating program the Burris RSC system was used. The procedures to access to this computer program are as follows:

1. login as

- a. Turn on the terminal;
- b. Hit <control>-D Prompt (USER & P)
- c. Enter user name <space><control>-D password <return>

2. Compiling the computer program "OPTIM"

- a. Free all memory;
- b. <SHIFT> <OPTIM> <return>
- c. V2.2 <return>
- d. NO EX <return>
- e. BEGIN <return>

3. Assigning each file to each storage

- a. AS 11-OPTOAC <return>
- b. AS 11-APP <return>
- c. AS 11-DETC <return>
- d. AS 11-DETC <return>
- e. AS 11-DETC <return>
- f. AS 11-DETC <return>
- g. AS 11-DETC <return>
- h. AS 11-DETC <return>

4. Execution

- a. AS <return>

BIOGRAPHICAL SKETCH

Yasir Dabb was born in Fasan, Korea, on May 29, 1950. He entered the Seoul National University in March 1970, and received the degree of Bachelor of Science from the Department of Applied Physics in 1974. After graduation, he joined the Republic of Korea Army from 1974 to 1976. He worked as a research engineer in the Agency for Defense Development for two and one-half years.

He started his graduate study in 1976, and received a Master of Science Degree in electrical engineering from the University of Florida in 1980. His fields of interest are electromechanical energy conversion and applications of magnetism.

I certify that I have read this study and that in my opinion it conforms to acceptable standards of scholarly presentation and is fully adequate, in scope and quality, as a dissertation for the degree of Doctor of Philosophy.

Alexander R. Nayatel, Chairman
Associate Professor of Electrical Engineering

I certify that I have read this study and that in my opinion it conforms to acceptable standards of scholarly presentation and is fully adequate, in scope and quality, as a dissertation for the degree of Doctor of Philosophy.

J. Kenneth Nelson, Co-Chairman
Professor of Electrical Engineering

I certify that I have read this study and that in my opinion it conforms to acceptable standards of scholarly presentation and is fully adequate, in scope and quality, as a dissertation for the degree of Doctor of Philosophy.

Glen T. Sigurd
Professor of Electrical Engineering

I certify that I have read this study and that in my opinion it conforms to acceptable standards of scholarly presentation and is fully adequate, in scope and quality, as a dissertation for the degree of Doctor of Philosophy.

Robert L. Sullivan
Professor of Electrical Engineering

I certify that I have read this study and that in my opinion it conforms to acceptable standards of scholarly presentation and is fully adequate, in scope and quality, as a dissertation for the degree of Doctor of Philosophy.

D. Yeager
Graduate Research Professor of
Mechanical Engineering

This dissertation was submitted to the Graduate Faculty of the College of Engineering and to the Graduate School, and was accepted as partial fulfillment of the requirements for the degree of Doctor of Philosophy.

August 1988

Dean, College of Engineering

Dean, Graduate School
